## PREFACE

The NOA'81 SEA ROVER experiment was carried out during Cruise 76 of FS "Poseidon" between the Azores, Greenland and the British Isles during the summer of 1981.

The experiment was part of a long-term research programme designed to investigate structures in the seasonal boundary layer. The spectral range covers over three decades in the horizontal ranging from the gyre scale (order 1000 km ) to the mesoscale (order 1 km ) and it includes finestructure with vertical scales of more than one metre. Covering this broad spectral range was only possible with the development of the "Seasonal and Regional Ocean Variability Explorer" (SEA ROVER). A detailed description of various parts of the system can be found in Fischer et al. (1985), Leach (1984) and Horch (1984).

Although these technical reports represent the present status of the system most of the parts were already operational in 1981. A brief description of the system including the data processing will be given within this report.

There were two main scientific targets:
(1) large-scale variability of the boundary layer between the Azores ( $38^{\circ} \mathrm{N}$ ) and $55^{\circ} \mathrm{N}$,
(2) three-dimensional mesoscale structure of the polar front near the Gibbs Fracture Zone.

Although the scientific applications were different, the data sampling, processing and reduction of this large data set was identical for both parts of the experiment, the products are, however, presented separately according to the scientific objectives.

Within this report we describe the experiment and data processing, assess the experimental errors and present a selection of the possible products from various stages of the data processing. Many of the diagnostic techniques were developed to analyse the Batfish data set collected from RRS "Discovery" during GATE (Woods and Minnett, 1979; Leach, Minnett and Woods, 1985). This data report does not offer scientific interpretation of the data. It is possible to gain some insight in the variability encountered in the seasonal boundary layer from the selection of products derived from routine computer processing of the data set.

## 1. INTRODUCTION

### 1.1 Aims of the experiment

The exploration of the thermohaline variability in the seasonal thermocline as a function of space and time in different hydrographic regions of the North Atlantic Ocean is a long-term aim of the research in the Regional Oceanography Department at IfM-Kiel. The "Seasonal and Regional Ocean Variability Explorer" (SEA ROVER) measurement system was developed to monitor these structures with the best possible resolution. The first use of this system was in the experiment called NOA ' 81 described in this report.

Scientifically the experiment was designed for two major problems:

## (a) Long Sections

The regional climate of the ocean boundary layer as a link between the atmosphere and the interior of the ocean is not yet well understood. The reason for that is the failure of the too scarce coverage of hydrographic measurements, mainly based on station data, to resolve the regional, seasonal and interannual variations.

The SEA ROVER system is a tool to improve data collection. It measures profiles of temperature, conductivity and horizontal velocities at the sea surface and records navigation and meteorological data while the ship is moving at full speed. The speed and the high horizontal resolution of the SEA ROVER system enable the surveying of large areas much more synoptically and with better resolution than classical station measurements do. Real-time data processing on board helps to reduce the enormous amount of data.

It is planned to use the ready-processed data set to study the system atmosphere - mixed layer - thermocline, for calculations of heat and fresh water budget and for investigation of seasonal cycles of various parameters for example, mixed layer depth, potential vorticity.

## (b) Frontal Structures

The mesoscale waveband in the spectrum of oceanic motion extends from the spectral peak of synoptic-scale motions (near the Rossby radius of deformation) to the spectral peak of microscale turbulence (at the Ozmidov scale). In the seasonal thermocline, the mesoscale waveband
ranges from about 30 km to 30 cm . This spectral band includes internal waves and the enstrophy cascade of isopycnic turbulence and finestructure in hydrographic profiles. Mesoscale jets and fronts are a key phenomenon In these latter processes.

The aim of this part of the experiment was to survey the threedimensional structure of thermoclinicity, baroclinicity, velocity and potential vorticity to spatial and temporal resolutions and accuracies commensurate with the processes described by the computer models (Onken, Bleck and Woods, 1985).

Surveying mesoscale fronts with a rapidly moving ship seems to be the best strategy to minimize the difficulties of interpreting the structures caused by non-synoptic or poorly-resolving measurements.

The experiment should take place in a region where the relevant quantities show strong signals, that means in a region with the best signal-tonoise ratio. Therefore we decided to choose the North Atlantic Polar Front as a good test site for these studies.

### 1.2 Experimental design

For the experiment the full capabilities of the measurement system were used. The towed fish undulation in the form of a saw tooth wave should reach clearly the mixed layer and dive as deep as possible into the seasonal themocine with $a$ minimum wavelength to resolve the expected steep temperature gradients. The ship should move at full speed of about $5 \mathrm{~m} \mathrm{~s}^{-1}$ to improve synopticity and save time during measurements. The data should be recorded and processed continuously.

## (a) Long Sections

For the investigation of the long sections the ship followed along standard tracks whose choice had both technical and scientific reasons. They are the links between the front survey area at the polar front, the supply base at the Azores and the home port. They pass through the location of the Ocean Weather Ships to provide a comparison of the data with the long-term measurements at the Ocean Weather Stations. Repeated measurements along the same standard tracks on return trips and in different seasons and years should allow investigations about persistence of features and seasonal and interannual varlations.
(b) Frontal Survey

A general survey pattern was designed to localize the synoptic-scale structures, meanders and eddies of the North Atlantic Polar Front and to find a region with high thermoclinicity, which is defined as the horizontal temperature gradient on an isopycnic surface. Then, focussing in on that region, a high resolution survey, which should resolve the mesoscale structures and cut the front as many times as the available ship-time allows, should be made. In order to control the experiment, real-time graphs of the thermoclinicity signal should be used to predict the orientation of the front for the following section.

The towed fish undulation in form of a sawtooth wave should cover the upper 80 metres of the structures with a minimum wavelength to resolve the expected high thermoclinicity. The ship's speed was aimed to be about 5 m s - in order to minimize the effect of non-synopticity in the measurements.

### 1.3 Experimental site and oceanographic conditions

Our Long Sections range from the Azores to about $55^{\circ} \mathrm{N}$ from the anticyclonic Subtropical Gyre well into the cyclonic Subartic Gyre, where the Polar Front is the boundary between these gyres, and from the Azores to the English Channel.

Both sections should intersect the streamlines of the North Atlantic Gyre (Dietrich, 1969). The mass transport across the Azores - Greenland section is concentrated in the region of the Polar Front otherwise known as the North Atlantic Current, between $48^{\circ} \mathrm{N}$ and $51^{\circ} \mathrm{N}$, whereas the Azores English Channel section is expected to cross the various branches of the recirculation between the Azores and the European continent (Dietrich et al., 1980).

Both sections cross the zero line of the net annual water flux resulting from precipitation minus evaporation (Baumgartner and Reichel, 1975).

Along the Azores - English Channel section the net annual heat flux through the surface is nearly zero while the Azores - Greenland section intersects the axis of maximum heat loss (Budyko, 1974).

The Azores - Greenland section follows the track of the long hydrocast section measured during the International Geophysical Year (Dietrich, 1969).

A recent summary of the seasonal and regional variation along our sections can be found in the Isopycnic Atlas of the North Atlantic Ocean (Bauer and Woods, 1984) which was derived from the well-known Robinson-Bauer-Schroeder Atlas (1979). The general structure during July and August is a welldeveloped seasonal pycnocline with a shallow mixed layer.

Winter mixing reaches deeper than 150 m in the whole region we surveyed. That means that the water column in the depth range of the towed fish all Ifes within the seasonal pycnocline.

### 1.4 Sonderforschungsberetch 133 - "Warm Water Sphere of the Atlantic"

Our work including the investigation of large-scale structures in the seasonal thermocline as well as frontal structures can be seen in the context of the long running "Warm Water Sphere" cooperative research programme (Sonderforschungsbereich) funded by the Deutsche Forschungsgemeinschaft (German Research Council). The aim of this programme is to gain some insight into the dynamics and thermodynamics of the North Atlantic, the transports of heat and mass from the western basin across the Mid-Atlantic Ridge into the eastern basin, and the recirculation in the subtropics.

Although many groups participate in this programme the interactions with the following groups are especially relevant to our work:

Satellite images of sea surface temperature at the Polar Front will help us to identify regions of strong thermoclinicity and give some hint of the time scales of the observed structures (Hardtke and Meincke, 1984). Surface fluxes af ter Isemer and Hasse (1985) based on Bunker's data will help us to interpret the large-scale variation of the seasonal thermocline.

From long sections with deep CID-stations along the Mid-Atlantic Ridge (Meincke and Sy, 1983) the maximum depth of winter mixing can be estimated by the "thermoclinicity elbow" method (Woods, 1985). Drifter trajectories (Krauss and Meincke, 1982; Krauss and Käse, 1984) will be used to identify the seasonsl catchment area of the water being advected through our area.

### 1.5 Publications and Reports

Bauer, J. and J.D. Woods (1984) Isopycnic Atlas of the North Atlantic Ocean. IfM Kiel Berichte Nr. 132.

The North Atlantic part of the numerical atlas produced by M. Robinson, E. Schroeder and R. Bauer (1979) from NODC data was used to present the annual cycle of the hydrography on density surfaces. Monthly mean temperatures were combined with annual mean salinities to calculate pseudo-monthly mean densities.

The first part presented monthly mean maps of the distribution of pressure, temperature and salinity on various density surfaces.

Vertical sections in isopycnic coordinates were presented in part two. They follow the standard ship's tracks of the SFB-133 TP-BI: Azores Greenland and Azores - English Channel.

Fischer, J., C. Meinke, P. J. Minnett, V. Rehberg and V. Strass (1985) A description of the Institut für Meereskunde Schleppfisch-System. Technischer Bericht Nr. 1, 2. Auflage.

This is a detailed technical description of the mechanics, electronics and software of the Schleppfisch-system. This report includes also an operating manual for the use of the Schleppfisch (towed fish) and the basic CTD data processing for quick-look data. Although this is a description of the present configuration of the system (1985), it is still relevant for the 1981 state.

Fischer, J., H. Leach and J.D. Woods (1985) Synoptic-scale structures in the seasonal thermocline at the North Atlantic Polar Front. (in preparation)

This is a description of synoptic-scale structures at the North Atlantic Polar Front measured with the SEA ROVER systen. This paper draws attention to the similarities between hydrographic data in the seasonal themociine and sea surface currents. Derived quantities such as relative vorticity and spacing between isopycnals show significant correlations.

Horch, A. (1984) Eine Beschreibung der NOVA-Software für Schleppfischexperimente.
Technischer Bericht Nr. 5, 2. Auflage.
This is a technical report about the CTD-data processing and editing on the shipboard minicomputer "NOVA-4C". The second edition describes the state of the software in 1984, but includes the 1981 programs. (in German)

Leach, H. (1984) Eine Beschreibung des wissenschaftlichen Navigationssystems des FS "Poseidon".

Technischer Bericht Nr. 2, 2. Auflage.
This is a description of the scientific navigation system based on an HP-1000 minicomputer, which was used in 1981 on board FS "Poseidon". This system is the basic tool for measuring sea surface currents by using both absolute and relative navigation. The second edition describes the state of the system in 1984, but the main concept remains unchanged.

Leach, H. (1985) The analysis of currents measured from a moving ship in the region of the North Atlantic Polar Front. (submitted)

Ship drift measurements were used to calculate sea surface currents independently from the hydrographic data. By using the relative vorticity, which was derived from the objectively analysed current field, it was possible to calculate the surface streamfunction. Synoptic-scale meanders were the dominant features in the streamfunction and some similarities with the thermohaline structures have been observed.

## 2. INSTRUMENTATION - The SEA ROVER

### 2.1 The towed undulating CTD-system as a concept

The investigation of processes in the upper ocean with strong variability in space and time, such as eddies and fronts, set a specification for the measurement system, which is not or not satisfactorily fulfilled by conventional profiling systems.

For studying such processes the measurement system should allow for synopticity combined with high resolution in the space and time scales. These scales cover a broad spectral range in both space and time. High accuracy and long-term stability of the calibration of the sensors is another important requirement.

Quasi-synoptic measurements can only be obtained from a moving ship, using freefall probes (XBT's, XSTD's) or towed, undulating systems.

In order to describe the kinematics and the dynamics of the ocean at least temperature and salinity as a function of depth have to be measured. These are the usual sensors of a normal CTD.

In contrast to any profiling from a stationary or slowly drifting ship, where a "true" vertical profile is obtained, a towed system will give the parameters as a function of the vertical and horizontal coordinates depending on the ship's speed and the descent/ascent rate of the system. This effect may distort the measured parameter field according to the inclination of the profile. High vertical speeds will minimize this distortion, but sometimes a correction will be necessary, which is only possible if the positioning of the system is very accurate.

The quintessence of all these requirements led to a system, which is derived from the Bedford Institute "Batfish" (Dessureault, 1976) and the LOS (Hormley) "Sea Soar" (Collins et al., 1983). It should carry a high resolution CTD with fast response sensors to reduce the time lag effects caused by the high penetration speed of the fish. Accurate navigation with the possibility of calculating positions relative to a moving body of water will complete the system, especially if the experiment requires quasi"Lagrangian" coordinates (Woods and Minnett, 1979).

The SEA ROVER system was used for the first time during the experiment NOA'81. According to the requirements described above, the system has three main tasks:

1) Continuous CTD data sampling with a towed system.
2) Collection of navigation data during the experiment in absolute and relative coordinates.
3) Real-time data processing.

### 2.2 The IfM towed fish system

One key part of the system developed at the Institut fur Meereskunde Kiel (IfM) is a towed depth-controlled underwater vehicle, which is a further development of the "Sea Soar" designed at the Institute of Oceanographic Sciences (IOS) in Wormley, England, which is itself a development of the original Hermes/Guildline "Batfish" (Dessureault, 1976).

The in components of this system are the vehicle with its hydraulics and underwater electronics, a CTD-probe and the control unit on board the ship. For illustration of the various tasks of the system see figure 2.2.1.

The nose, tail-plane and wings of the towed fish are made from fibre-glass-reinforced polyester resin, whereas the fuselage is constructed from stainless steel. The latter holds the wing axle and the fittings for the electronics pressure vessels and the hydraulics unit. The wings are mounted on a horizontal axle so that their angle relative to the fuselage can be varied to cause the fish to climb or dive.

In order to reduce rolling of the fish, a stabilizing fin is freely hinged at the tail (Dessureault, 1976) (see figure 2.2.3).

The fish contains two pressure vessels, one for the control electronic and the other being the CTD underwater unit. The hydraulics are contained in a cylindrical oil bath which is pressure-equalized with the surroundings. The control electronics are based on those developed at the Forschungsanstalt für Wasserschall- und Geophystk der Bundeswehr, Kiel (FWG). This unit performs four tasks:
(1) monforing the parameters which describe the condition of the fish, i.e. depth, wing angle, roll and pitch angles;
(2) transuicting these data to the control unit on board the towing ship;
(3) receiving and decoding the command signal from the control unit;
(4) generating the analogue signal to control the Moog-servo-valve which determines the wing movement.

A separate strain-gauge pressure cell is used to monitor the depth of the fish, in order to enable the fish to be controlled independently without recourse to the pressure signal from the CTD. This modularization of the system, making the fish independent of the payload, proved useful in practice particularly during the development phase.

A very durable hydraulic system (based on that used in the IOS Sea Soar: Collins et al., 1983) drives the tilting of the wings. This system is designed to allow long tows (approximately 1000 hours between routine services), and due to the high oil pressure of up to 7 MPa , an immediate response to the command signal generates sharp turning points in the fish profiles. The oil pressure is provided by a pump driven by an impeller at the back of the fish turned by the water flowing past it.

The generation and transmission of the command signal is one task of the control system on board the ship, which also monitors the attitude of the fish and uses the data supplied by the payload (CTD-probe), to calculate salinity and density. The system described and its software is developed from those of the FWG-controller. There are two operating modes, manual and automatic. In manual mode, used only during deployment and recovery of the fish, the wing angle is adjusted by the setting of $a$ hand-operated potentiometer. In automatic mode, the controller guides the fish along a sawtooth track between maximum and minimum depth with a constant dive- and climb-rate, all chosen by the operator. The control algorithin tries to minimize any deviation fron the desired track. In order to control the fish independently from the payload (CTD) a separate pressure gauge is used, which is part of the control electronics.

The fish was towed on a 10 mm diameter single core towing cable, fixed by a bridle to the fish. This cable was unfaired and has a nominal breaking strain of six tonnes. All signal transfer to and from the underwater untt and the current supply was carried along this cable. Three frequency bands were used, one for the control signal to the fish, one for the fish parameter to the ship and one for the CTD data to the ship. The cable was paid out from the towing winch on FS "Poseldon" using the A-Frame and the Geological Boom as shown in figure 2.2 .2 . In normal towing operation the boom is in its resting position. Only during deployment and recovery the boom is extended and the cable removed from the snatch block on the port side of the A-Frame.

The payload in 1981
The CTD-probe in the towed fish was a slightly modified ME-Kompakt-Sonde from "Meerestechnik Elektronik GabH, Trappenkanp". In order to resolve swall-acale temperature and salinity gradients, the sensors should have high resolution and accuracy, and a quick response. For quality control of the data two thermometers and conductivity cells plus the possiblity to display the measured differences we needed. Table 1 shows the specifications of the gensors as given by the manufacturers.

Table 1 - Table of sensor specification ME-Multisonde

| PAMANETHES | SPECLFICATION |
| :---: | :---: |
| Pressuat | Principle : Strain-gauge pressure cell <br> Range : 0-600 dbar <br> Resolution : 0.01 dbar <br> Accuracy : $0.25 \%$ of range |
| TEMPERATURR | Principle : Platinum resistance Range $:-2-+40{ }^{\circ} \mathrm{C}$ Resolution : $0.001{ }^{\circ} \mathrm{C}$ Accuracy $: 0.005^{\circ} \mathrm{C}$ |
| CORDUCTIVITY | Principle : Symatric electrode cell Range $: 5-55 \mathrm{mS} / \mathrm{cm}$ Resolution : $0.001 \mathrm{mS} / \mathrm{cm}$ Accuracy : $0.005 \mathrm{~ms} / \mathrm{cII}$ |

Temperature and conductivity sensors were mounted in pairs on the lower tail plane of the fish, figure 2.2.3, whereas the strain-gauge pressure cell is directly fixed to the CTD-vescel inside the towed fish. The sampling rate, which was used in the NOA' 81 experiment was 16 cycles per second, equivalent to s time interval of 62.5 ms between each data cycle, each of which consists of one pressure, two temperature and two conductivity measurements.

The raw data from the CrD-probe we converted into 16 -bit words by the microprocessor controller and then archived on a nine-track digital tape, followed by trailer information about time and dive-climb orfentation after every 50 data cycles.

To allow quick-look analysis of the data, every sixteeath cycle (i.e. one cycle per second) was tranaformed into physical unita, and salinity and
density were calculated. All values were displayed on the front panel of the controller, and a subsample, chosen by the operator, was available on analogue output channels.

### 2.3 The "Poseidon" Navigation System

The NOA'81 expedition was the first expedition in which the "Poseidon" navigation system was used to collect and store navigation data. This system serves exclusively as a scientific aid and is not used for the routine ship navigation. The system is based on a Hewlett-Packard HP1000 minicomputer to which many of the ship's navigational instruments are interfaced as shown in figure 2.3.1. During this cruise the computer was running under a version of the RTE-MIII operating system with 64 K memory. This allowed a maximum of three partitions which in turn limited the number of programs which could run in parallel to three. So three tasks could be performed in real-time: first the acquisition of satellite-navigation positions from the Magnavox MX1105, second the integration of the ship's position relative to the water using the Colnbrook electromagnetic log, and third displaying the navigation in alphanumeric and graphic form on the system's graphic terminals.

Spot values of all the available navigational parameters were printed out and stored on disc every two minutes. The data on disc were then transferred to magnetic tape two or three times a day as necessary for merging with the data from the towed fish.

The electromagnetic log was calibrated off the Azores on 18th July 1981 using a drifting radar-buoy with a sail centred at the depth of the log (ca. 4.5 m ). The fore-aft and port-starboard components were calibrated separately. The detalls of the method used are contained in Leach, 1984. This was a third set of coefficients obtained which were accordingly stored in a file named FKAL3.

Table 2.3.1 lists the programs used during the NOA ' 81 expedition.

Table 2.3.1 - Programs used on the "Poseidon" navigation system during NOA'81

| SATNA | acquisition of satellite navigation data |
| :---: | :---: |
| EMLOG/EMLO2(TE) | acquisition and integration of electromagnetic $\log$ signal |
| PLOTT/PLOT2(TE)/PLOT3(TE) | output of alphanumeric and graphic data to terminals |
| CHK2M | correction of 2-minute data on disc |
| $\left.\begin{array}{l} \text { H2MTP } \\ \text { H2MTQ } \end{array}\right\}$ | transfer of 2-minute data fron disc to tape |
| EMXAL | caltbration of electromagnetic log |
| DECCA/DECC2(TE) | Decca navigation |

Note: Those programs followed by the letters (TE) ran under timed execution and were scheduled by the operating system whereas the others were free-running.

### 2.4 Data acquiaition and real-time monitoring

To conduct an experiment for mesoscale frontal studies means not only to have a suitable measurement system, but to obtain information about the spatial structure of the phenomenon in almost real-time. This led to the real-time data processing scheme, shown in figure 2.4.1. "Real-time" in this context means to get the desired results, for example, plots of temperature distribution on density surfaces, in a time interval, which is equivalent to that of data acquisition. In the first gtage, the raw fish data and the navigation data were merged and interpolated to the same time interval. The data were then separated into ascending and descending profiles. For the real-time analysis only the descending part was used for further block averaging and transformation to physical units. In addition salinities and densities were calculated, and the result is stored on digital tape.

In the third stage the variables were interpolated onto standard surfaces, e.g. temperature and pressure on constant density (or and density on temperature.

These products were plotted afterwards, to allow necessary data analysis.

## 3. THE EXPERTMENT

The long-term field programme was designed to make a series of long sections measuring the temperature, salinity and density field in the seasonal boundary layer during different seasons of the year. A detailed study of the three-dimensional thermohaline variability at the North Atlantic Polar Front was incorporated in these long sections.

The undulation of the fish was set to a sawtooth waveform with turning points close to the surface and at 80 metres. A ship's speed of about 4-5 metres per second and a mean ascent/descent rate of 2 metres per second gave a wavelength of about 500 metres. A typical example of the track is shown in figure 3.1.

The data sampling rate ( 16 data cycles per second) gave a mean vertical resolution of 12.5 cm .

### 3.1 The Long Sections

For the long sections we chose two standard tracks which were planned to be surveyed in different years and at different seasons (figure 3.1.1).

The Azores - English Channel section starts at the shelf edge of the western approaches to the English Channel at about $48^{\circ} 15^{\circ} \mathrm{N}, 10^{\circ} 40^{\prime} \mathrm{W}$, passes through the position of Ocean Weather $\operatorname{Ship}$ " $\mathrm{R}^{\prime \prime}$ at $47^{\circ} \mathrm{N}, 17^{\circ} \mathrm{W}$ and finishes at the eastern end of the Azores' island Sáo Miguel at $37^{\circ} 50^{\prime} \mathrm{N}$, 24*50'W.

The section Azores - Greenland starts at the western end of Sao Miguel at $37^{\circ} 50^{\prime} \mathrm{N}, 25^{\circ} 55^{\circ} \mathrm{W}$ heading towards the southern end of Greenland, avoids the direct pass over of the relatively shallow Chaucer Bank at $43^{\circ} \mathrm{N}, 29^{\circ} \mathrm{W}$, by passing through the point $43^{\circ} \mathrm{N}, 30^{\circ} \mathrm{W}$ and passes Ocean Weather ship "C" at $52^{\circ} 40^{\prime} \mathrm{N}, 35^{\circ} 30^{\circ} \mathrm{W}$ and contimues in the same direction until the $10^{\circ} \mathrm{C}$ isotherm reaches the surface, which was found in 1981 at $55^{\circ} \mathrm{N}, 37^{*} \mathrm{~W}$.

The high spatial resolution covers a spectral range from 2500 km which is the length of a standard section to the Nyquist wave length of 1 km , which was twice the distance between single profiles. With this range gyrescale, eddy-scale as well as mesoscale structures are resolved.

The depth range from $0-80 \mathrm{~m}$ includes the wixed layex and the diuraal themocline and at least in the sumber the upper part of the seasonal
thermocline. As the system works at full ship's speed of about $5 \mathrm{~ms}^{-1}$ the measurements are as synoptic as reasonably possible. The high data density ensures the observed structures a high statistical significance.

The timetable of the 1981 expedition allowed comparison of measurements of the same area in a time range of single days to 2 months (figure 3.1.2). The time interval between the northward and southward leg of the AzoresGreenland section is only some days north of the Polar Front and about 2 weeks south of it. The return leg from the Azores towards the English Channel ( 10 th to 18 th September) was made 2 months later than the outward leg (14th to 18 th July).

### 3.2 The Polar Front Survey

The area for the frontal survey was roughly fixed during the long section B102 from the Azores to the outcrop of the $10^{\circ} \mathrm{C}$ isothem at about $55^{\circ} \mathrm{N}$. The region of strongest horizontal thermohaline contrast was found near $51^{\circ} \mathrm{N}$, $35^{\circ} \mathrm{W}$ in the vicinity of OWS "C". This region was thought to be the edge of the warm water sphere, separating the relatively warm water of about $15^{\circ} \mathrm{C}$ at the surface from the relatively cold water with $11{ }^{\circ} \mathrm{C}$ or less. The sea surface salinity decreased from $35.4 \times 10^{3}$ to less than $34.8 \times 10^{3}$ within 50 kilometres.

A set of two east-west sections (C301, C305 combined with C303) each about 400 kilometres long (figure 3.2 .1 ) should give some information about the principle synoptic-scale structures in this region. These sections form a nearly rectangular box of $400 \mathrm{~km} \times 200 \mathrm{~km}, 5^{\circ} \mathrm{W}$ of the Mid-Atlantic Ridge south of the Gibbs-Fracture-Zone.

A more detailed study of the frontal structures was carried out at $51^{\circ} \mathrm{N}, 35^{\circ} \mathrm{W}$. This part of the experiment consists of 10 sections, each about 75 km long and about 10 km apart. These sections were orientated almost perpendicular to the axis of the front. Unfortunately the original orientation had to be changed after section $C 312$ due to bad weather conditions.

Table 3.1 shows a summary of all NOA'81 sections with start and end position, start and end time and the mean ship's heading.

In addition to the sections, a deep ( 600 m ) section with conventional CTD dips was carried out to explore the vertical extension of the observed features.

Table 3.1: List of all NOA' 81 SEA ROVER sections with gtart and end time, start and end position, and the nominal ship's heading.

## 4. PROCESSING AND REDUCTION OF HYDROGRAPHIC DATA

A flow diagram of the data processing and its products is presented in figure 4.1. The processing described in this chapter is that used on land after the experiment.

### 4.1 CTD raw data recording

The signals from the pressure sensor, the two temperature and the two conductivity sensors of the CTD-payload were digitized in the underwater unit and written on tape in blocks of 25616 -bit words. 250 words contain 50 cycles with raw numbers from the five sensors stored at the interval of 62.5 ms followed by a 6-word trailer containing the start time of the block and an up/down flag indicating whether the fish was climbing or diving.

### 4.2 Navigation data recording and correction

On the navigation computer a permanent random access file was arranged with 720 records, one for each 2 -minute interval of the day. Every 2 minutes the file was updated with the current navigation data. Absolute and relative navigation data stored in this day-file were dumped onto magnetic tape twice a day for archiving. The ship's drift between satellite fixes was uniformly distributed over the track integrated by the EM-log. Program NAGUT corrected the navigation data between satellite fixes.

### 4.3 Merging navigation and CTD raw data (lst processing)

The program for the first processing stage called VMRAN formed a time basis by extrapolating the start time of a CTD raw data block for the next 50 cycles by integrating the sampling interval. It searched for the matching 2 -minute interval in the navigation files and interpolated the positions linearly. Thus for every 62.5 ms a cycle was created containing explicitly the time, the raw values from the CTD-sensors, the navigation values and the up/down flag.

### 4.4 Calibration, editing, data reduction, and calculation of derived variables (2nd processing)

In order to minimize the number of output tapes calibration of CTD raw values, editing spikes, data reduction and calculation of derived values were handled by one program called MEDIT.

A time constant correction was applied to the temperature values in order to minimize the mismatch between the temperature and conductivity measurements. Empirical tests yielded a time constant of 85 ms needed to reduce the salinity spikes caused by this mismatch. A description of these tests is given in section 5.2 . Then the raw values from the CTD sensors were transformed into physical units using laboratory calibration coefficients in a second order polynomial.

Salinity was calculated from pressure, temperature and conductivity and then filtered with a median-filter (Sy, 1985) with a 5-cycle window to remove spikes without eliminating strong gradients. The data was then averaged over five cycles. The averaged temperatures and salinities were used for the calculation of $f$ for each sensor pair respectively.
4.5 Pressure motonisation and up-down splitting (3rd processing)

Experience from former Batfish experiments (GATE, Leach et al., 1985) showing significant differences in the signals of the ascending and descending parts of the fish track which suggests separating them. As the fish did not follow exactly the control signal, the turning points had to be determined from the data. Program TURNP performed the following processing.

The up/down-flag, which changed when the control signal switched from dive to climb up or vice versa, could be used as a criterion for starting the search for the next pressure maximum or minimum within a limited number of cycles. During the separation of ascents and descents, cycles which were not monotonous in pressure were dropped. A plausibility check of the hydrographic data also removed single senseless values caused by parity errors in the raw data and substituted them by the preceding value.

The profiles were counted and the number was stored as a label in each data cycle, even numbers for descents, odd numbers for ascents. Ascents and descents were stored in separate files.

### 4.6 Calibration correction of salinity and pressure (4th processing)

The calibration of the conductivity sensors in the laboratory was not sufficiently exact. The salinities of the hourly samples had to be used for a correction of the calibration. The water sample salinities were compared with CTD salinities in space and time. Using a linear regression performed by program LINREG, correction parameters for a linear transformation were calculated (figure 4.6.1). The calibration of pressure also had to be corrected. This was achieved by using the distribution of pressure at the upper turning point (figure 4.6.2). The pressure values showed a temperature dependent negative offset $\Delta P(T)$.

$$
P_{\text {corr }}=P+\Delta P(T)
$$

The pressure was corrected by adding the offset for the mean surface temperature of a 4-hour file. Using program EICH3 salinity and pressure were corrected and density was recalculated within the new calibrated salinities.

### 4.7 Elimination of small density inversions (5th processing)

At this stage density was contaminated by inversions due to salinity spikes which could not be removed by the preceding editing methods. A medianfilter with a 5-cycle window on density was used to reduce as much of the small-scale noise as possible. Bigger inversions which were observed mainly at the bottom end of the profiles were thought to be an artifact of the slope of the fish-track and therefore they should be eliminated in the 6 th processing. For consistancy the salinity was recalculated from temperature and the filtered density. The filtering was done with program MEDFIL and yielded the clean data set, the basis for various further analysis.

### 4.8 Monotonisation and vertical interpolation (6th processing)

For isopycnic analysis the profiles were monotonized in density and interpolated on constant $\sigma_{\mathrm{t}}$-intervals of $0.025 \mathrm{~kg} \mathrm{~m}{ }^{-3}$ with program MONINT. Vertical interpolation onto constant pressure values was performed at intervals of $1.0 \times 10^{4} \mathrm{~Pa}$. Isopycnal or isobaric surfaces were extracted from the vertically interpolated profiles by apending and extraction routines EDIT2 and EXTRAC.

### 4.9 Calculation of spacing between isopycnals (7th processing)

Using program PRESDF isopycnal spacing was determined by calculating the pressure differences between $\sigma_{t}$ surfaces which were $0.1 \mathrm{~kg} \mathrm{~m} \mathrm{~m}^{-3}$ apart, within the same routine the depth of each isopycnal relative to a chosen reference isopycnal was calculated.
4.10 Objective analysis (8th processing)

The objective analysis method applied to this data set is described in Woods et al. (1981). Briefly, the method works as follows: Firstly the twodimensional auto-correlation function (biased) of the data to be analysed was computed. A weighting function (fig. 4.10) was derived by smoothing this raw auto-correlation function, multiplying it by a conical taper and setting negative values to zero. This weighting function would reach a value of zero within a finite number of grid lengths, normally less than eight, depending on the correlation distance. The weighting function was then used in a successive-correction objective analysis scheme. In order to avoid influencing the results by statistics with different characteristics the computation of the weighting function carried out separately for each parameter and each surface. The applied program for objective analysis was called OBANA.

DATA PROCESSING FLOW DIAGRAM

Fig. 4.1: Flow diagram of the data processing of the towed fish - CTD - data. Ovals contain stored processing stages, rectangles are programs and rounded boxes indicate standard products.

Fig. 4.6.1: Linear regression of salinities of salinometered water samples and raw calibrated CTD-data presented sepaxately for each sensor pait. The slope and offset of the regression cuyve stom the final calibration of CTD-salinities.

Fig. 4.10: Examples of weighting functions of temperature and depth of isopycnal of $26.5 \mathrm{~kg} \mathrm{~m}^{-3}$, derived from raw autocorrelation functions of the frontal survey.

## 5. ANALYSIS OF ERRORS

Before starting to present the results of the data analysis, the careful error analysis carried out is discussed in this chapter.

### 5.1 Measurement errors and corrections applied during data processing

In all CTD measurements, random errors arise from the electronic noise and the digitizing interval. Systematic errors have been caused by the response time of the sensors due to rapidly changing fields and by the inaccuracles involved in the calibration of the sensors.

An ME-Multisonde was used (MS 38) which was equipped with one pressure gauge and pairs of thermometers (Rosemount PT 200) and large conductivity cells. The accuracies guaranteed by the manufacturer are listed in table 1. Due to technical reasons we reduce the orginal 16 -bit resolution to 15 bit, which led to a digitizing interval of $2 \mathrm{mK}, 0.002 \mathrm{mS} / \mathrm{cm}$ and 0.02 dbar for the thermometers, conductivity cells and the pressure gauge.

The systematic errors occuring turned out to be much more important then these random inaccuracies, which we can therefore neglect in our error analysis.

A major problem for the accuracy of the measurements was the inefficient calibration. The sensor calibrations were carried out by the manufacturer and it turns out, that they over-estimated the accuracy. For pressure and salinity a way was found to improve the calibration, for temperature no correction could be found for the inaccuracies detected by comparing both sensors with each other.

The other important source of inaccuracy was the heat flow, especially in the themometers and the pressure gauge.

Temperature and conductivity were measured with two sensors each. As both sensor pairs can be treated as independent measurements of the same water, the analysis of the difference between them gave us additional information about the accuracies and the impact of applied correction and editing methods upon the measurements.

In the following sections the problems and the attempt to solve them are described for each parameter respectively.

## Pressure

A systematic error of the pressure measurement is caused by the rapid change of temperature of the surrounding water. The pressure strain gauge of the CTD-probe is mounted inside the fish's hull. Its good thermal contact to the pressure vessel which has a much larger thermal capacity than the sensor itself damp the temperature change of the sensor.

Sma11 holes on the side of the fish's body provide the contact of water inside with the outside. Although we have no quantitative measurement of the temperature in the interior of the fish, we assume the temperature range outside the fish of 5 to 8 K between the turning points of a proftle to be suppressed by a factor of three, which is supported by the results of an earlier test cruise. The error in the pressure signal could be estimated to approximately $0.1 \times 10^{4} \mathrm{~Pa} / \mathrm{K}$.

We decided to treat the ascending and descending parts of the fish track separately to get consistant data sets which are not affected relatively by this systematic error.

The effect of dynamic pressure, caused by the passage of the fish through the water is also a systematic error estmated for a towing speed of $5 \mathrm{~m} \mathrm{~s}^{-1}$, according to $\mathrm{p}=1 / 2 \mathrm{\rho a}^{2}$ is of order $1 \times 10^{4} \mathrm{~Pa}$.

The calibration of the pressure sensor done by the manufacturer turned out to be incorrect. It showed a negative offset. The fact that the towed fish often reached the sea surface allowed this error to be corrected. A scatter diagram of the pressure at the upper turning points versus the temperature along the sections was plotted (figure 4.6.2). It was assumed, that the minimum pressure at different temperature values is the sea surface pressure, a statement which is supported by frequent sightings of the fish at the surface. The solid line in this graph was used to correct the data by shifting the whole profile according to its sea surface temperature value. To overcome the difficulty that not all profiles reached the surfaces the profiles of each four-hour section were shifted equally according to the four-hour mean surface temperature. We also took account of the fact, that the pressure sensor is 0.7 m below the top of the fish.

Taking these details into account yields an absolute error of $\pm 0.2 \times 10^{4} \mathrm{~Pa}$ around the upper turning point where the sea surface is a relatively well-defined reference level. In the deeper layers the uncertainties increase towards the lower turning point where the combination of
thermal effects, sensor-lag, calibration uncertainties, and dynamical pressure add up to an error of $\pm 1.6 \times 10^{4} \mathrm{~Pa}$.

## Temperature

Before the calibration of the temperature signal in the 2 nd processing stage, a simple time constant correction for the thermometers was carried out. The algorithm applied to the data is shown in the following equation;

$$
T=T_{\mathrm{m}}+\tau \frac{\Delta \mathrm{T}_{\mathrm{m}}}{\Delta t}
$$

where $T_{m}$ is the measured temperature and $\tau$ the time constant of the thermometer. This time constant was estimated empirically by trying to reduce the spikes in the computed salinity signal. A time constant of about 85 ms (1.36 raw data cycles) was found to be most appropriate. This value is supported by the values given by the Rosemount company of about 120 ms . Nevertheless it was not possible to get rid of all salinity spikes and so it was decided to edit salinity separately.

By horizontally averaging mean and standard deviation profiles of the difference $T_{1}-T_{2}$ were calculated. They are presented in fig. 5.1.la using raw data and in fig. 5.l.ld calculated from data that had passed all data processing stages. A systematic mean difference of -10 mK limits the quality of the calibration. Why the difference becomes positive in the high gradient zone around 20 m is not understood. Randomly distributed differences were found along the whole profile, increasing proportionally with the local vertical temperature gradient.

These differences can be produced alone by rolling movements of the fish, because their magnitude is consistent with the observed roll angles and the vertical temperature gradient.

The comparison of fig. 5.1.la and fig. 5.1.1d show that the data processing did not change the statistics of the temperature measurement. The mean profiles are identical considering the dep th shift due to correction of the pressure offset. The standard deviation is slightly diminished after block averaging.

It is not clear how the temperature changes along the sensor cables, which were partly inside the fish, will effect the measurements, but it was
assumed to be negligible. From the manufacturer of the CTD sonde we received the following accuracies:

$$
\begin{array}{ll}
\text { Absolute accuracy } & \pm 10 \mathrm{mK} \\
\text { relative accuracy } & \pm 3 \mathrm{mK}
\end{array}
$$

## Conductivity

The main source of error in the conductivity signal is due to calibration inaccuracies. It was assumed, that the temperature effect was negligible and fouling by drifting material does not occur. We did not try to correct the conductivity itself, but the salinity as described in the following section.

## Salinity

It was mentioned above that the calibration of the conductivity sensors turned out to be inaccurate. To improve the accuracy we compared salinities of water samples, taken every hour at hull depth with CTD-salinities matching in time and space. Data pairs from regions with high vertical or horizontal gradients were rejected. Data from low variability regions were used for a linear regression (fig. 4.6.1) calculating the coefficients for a Iinear transformation to correct the measured salinity values. The residual of the regression analysis was $0.023 \times 10^{-3}$.

The mismatch in the response of the thermometers and conductivity cells was the most severe problem in the data set. The time lag of the thermometer caused by a time-constant of about 120 ms (a value given by the manufacturer) is an intrinsic property of the sensor, whereas the water-exchange time in the conductivity cell is a function of electrode spacing and the speed at which the fish penetrates the water. We decided to use an empirical method to minimize these effects by applying a temperature time constant correction of $r=0.085 \mathrm{~s}$. This value was determined by minimizing the difference in temperature and salinity at those parts of the ascending and descending parts of the profiles, which were close to the turning points of the fish. In these regions, horizontal differences in the parameters should be sall. The second criterion for the choice of this value was the symmetrical distribution of the remaining salinity spikes along the mean profiles.

This correction also reduced the size of salinity spikes but could not eliminate them all. We decided to use a median filter (Sy, 1985), a technique
which eliminates spikes but does not affect sharp gradients. The width of this filter was chosen to have a minimum effect on the statistics of the profiles. Furthermore we block-averaged the data over the range of the filter width.

Another use of the median filter upon density and a rewiteration of salinity from temperature and filtered density did not have much effect in the improvement of the data.

In spite of this editing scheme there are still remaining single spikes mainly in the zone of high vertical gradients just below the mixed layer which was also the region of maximum diving speed. Most of the remaining spikes have magnitudes less than $0.02 \times 10^{-3}$ and only very few spikes exceed $0.07 \times 10^{-3}$.

The effect of all the correction procedures on the salinity data can be seen by comparing raw data and ready processed average profiles of the difference $S_{1}-S_{2}$ (fig. 5.1.1b and fig. 5.1.1.e). The recalibration shifted the mean profile towards the zero line. Its vertical structure was not changed significantly. The deviation from zero remains less than $0.01 \times 10^{-3}$ at the upper boundary of the thermocline and values between 0.02 and 0.015 at the deeper parts to values around $0.01 \times 10^{-3}$, which is in the order of magnitude which could be expected for differences due to rolling of the instrument.

The comparison of water sample salinities with the edited CTD-salinities along section B102 (figure 5.1.2) shows to which extent the absolute accuracy of salinity could be improved. The difference between sensor pair 1 and sensor pair 2 remains mainly within the limits of $\pm 0.01 \times 10^{-3}$. The water sample-CTD-differences do not exceed $\pm 0.01 \times 10^{-3}$, except in regions of high horizontal gradients, where the non-perfect synchronization of sampling and CTD-measurements may have led to a mismatch in the resulting salinities.

## Density

The errors in the density $\left(\sigma_{\mathrm{f}}\right)$ are an accumulation of the errors of temperature and salinity since density is a function of salinity and temperature

$$
\varepsilon_{\sigma_{t}}=\frac{\partial \sigma_{t}}{\partial s} \varepsilon_{s}+\frac{\partial \sigma_{t}}{\partial T} \varepsilon_{T}=
$$

with $\varepsilon_{B}=0.02 \times 10^{-3}$ and $\varepsilon_{T}=0.01 \mathrm{~K}$ the errors in salinity and temperature. Tests for different regions and different vertical gradients reveal values of $\varepsilon_{\sigma_{t}}$ to be less than $0.005 \mathrm{~kg} \mathrm{~m}^{-3}$.

As for temperature and salinity mean profiles of the differences $\sigma_{t 1}-\sigma_{t 2}$ are presented in fig. 5.1.1c and 5.1.1f. As with salinity the editing reduces the variability of the sensor differences to the rolling range.

### 5.2 Humerical estimation of uncertainties in derived quantities.

Derived quantities such as salinity and density were influenced by the different time response of thermometers and conductivity sensors. Following various non-analytical stages in the data processing scheme, the uncertalnties in the derived variables can only be estimated by a numerical experiment. Therefore a synthetic set of profiles of temperature and salinity were generated and from these the corresponding conductivity profile was derived. The shape of the profiles were as close to the observed profiles as possible, although they are simplified due to their analytical construction. The salinity profile was constant with depth and the initial temperature profile has a mixed layer and decays exponentially below 20 m with realistic vertical gradients. The initial set of profiles is shown in figure 5.2.1.

The time constant of the thermometer was given by the Rosemount Company to 120 milliseconds and in a simple laboratory test this value was proved to be accurate.

The flushing time of the conductivity cell varies with the penetration speed of the fish. Typical parameters were a towing speed of $5 \mathrm{~m}^{-1}$ and a diving rate of $2 \mathrm{~m} \mathrm{~s}^{-1}$ resulting in a flushing time of about 10 milifseconds .

With these values in wind, we filtered the initial temperature profile according to:

$$
\begin{equation*}
T=T_{m}+\tau_{T} \frac{\partial T_{m}}{\partial t} \tag{5.2.1}
\end{equation*}
$$

where $T$ is the initial temperature, $T_{T}=110$ milliseconds the difference in the response characteristic between temperature and conductivity and $T_{m}$ the resulting (measured) temperature.

In finite differences this equation is written as

$$
\begin{equation*}
T_{(i)}=T_{m(i)}+\frac{T_{I}}{\Delta t}\left(T_{m(i)}-T_{m(i-1)}\right) \tag{5.2.2}
\end{equation*}
$$

with $\Delta t=62.5$ milliseconds given by the sampling rate of the CTD. From this equation an expression for $T_{m}(i)$ was derived:

$$
\begin{equation*}
T_{m(i)}=\frac{1}{1+\alpha} T_{(i)}+\frac{\alpha}{1+\alpha} T_{m(i-1)} \tag{5.2.3}
\end{equation*}
$$

with $\alpha=\frac{t}{\Delta t}=$ constant.

The initial condition for $T_{m(i)}$ with $i=1$ is given by $T_{m(1)}=T_{(1)}$, which is true for the mixed layer. The conductivity profile remains unchanged. The data were processed following the scheme of the data processing flow diagram (figure 4.1 ) and at each stage the resulting salinity and density profile was compared with the initial profiles. Two numerical experiments were carried out, the first with a constant diving rate of $2 \mathrm{~ms} \mathrm{~s}^{-1}$ and the second with a non-unfform diving rate, which varies between $1 \mathrm{~m} \mathrm{~s}^{-1}$ and $4 \mathrm{~m} \mathrm{~s}^{-1}$ with the maximum speed in the region of the strongest vertical gradient (at 20 m ). The diving rate in the second experiment was tuned to be similar to the diving characteristics of the fish during the NOA'81 expedition. The first step in the data processing was the application of the empirically estimated time constant $\tau=85$ milliseconds to the temperature data. Figure 5.2 .2 shows the salinity difference between the inttial profile and the derived salinity for both experiments. In this stage (Ia for constant diving speed) the variable diving rate (IIa) led to an increase of the maximum salinity error by a factor of two. The range, in which the salinity error exceeds $0.01 \times 10^{-3}$ is concentrated in the top 8 m
of the thermocline for case (Ia) and about 15 m for case (IIa). The median filter (Ib, IIb) had no effect on these profiles, but the following block average (figure Ic, IIc) can shift the 'error region' into the mixed layer which might lead to an error in the determination of mixed layer depth.

Remaining inversions in the density profile caused by the weak slope of the fish-track at the lower turning points were eliminated by applying the median filter also to the density profile, and salinity was re-iterated from the resulting density and the temperature profile (figures Id, IId). The results of this experiment are shown in figure 5.2 .3 where $\varepsilon_{s}$, the error in salinity is plotted as a function of $\partial T / \partial z$. For case (I) with a constant diving rate of $2 \mathrm{~m} \mathrm{~s}^{-1}$ the error in salinity is a linear function of the rate of change of temperature, and $\varepsilon_{s}$ is only greater than 0.02 in regions, where $\partial T / \partial z$ exceeds $0.45^{\circ} \mathrm{Km}^{-1}$. For case (II) the salinity error exceeds 0.02 at $\partial T / \partial z$ greater than $0.25^{\circ} \mathrm{Km}^{-1}$.

Temperature gradients of this magnitude ( $0.25^{\circ} \mathrm{K} \mathrm{m}^{-1}$ ) were observed not only at the top of the pycnocline, but the anomalously high diving rates were only at present in the top 30 m of the fish track, whereas in the remaining parts of the profile the diving speed was about $2 \mathrm{~m} \mathrm{~s}^{-1}$. Therefore errors in salinity caused by the nonperfect time-constant correction were estimated to be less than $0.02 \times 10^{-3}$ for the major fraction of the profiles, and only very close to the top of the seasonal thermocline the error may reach $0.05 \times 10^{-3}$.

Where temperature inversions occur, the error in salinity is expected to be less than $0.02 \times 10^{-3}$, assuming that the diving rate was about $2 \mathrm{~m} \mathrm{~s}^{-1}$ over the depth range of the inversion.

The density profile is also influenced by the mismatch in the time response of the thermometer and conductivity cell. Therefore the same procedure was carried out for density and the result is shown in figure 5.2.4. The errors in density were remarkably reduced during the processing stages; nevertheless the maximum error in density is $0.025 \mathrm{~kg} \mathrm{~m}^{-3}$ at constant diving speed (figure 5.2 .3 case Id) and about 0.05 kg m at variable diving speed. This error is limited to the top of the pycnocline and case IId can be treated as a worst case example for the top 10 metres of the pycnocline. Everywhere else the error in density would be less than $0.01 \mathrm{~kg} \mathrm{~m}^{-3}$.

The errors in the density profile would also influence the spacing between pairs of isopycnals, which were derived in the 7 th processing stage
(figure 4.1). Firstly the interpolation onto standard density surfaces being $0.025 \mathrm{~kg} \mathrm{~m}^{-3}$ apart was carried out for the initial density profile and the final editing stage. Afterwards the pressure difference between density surfaces being $0.1 \mathrm{~kg} \mathrm{~m}^{-3}$ apart was determined, and the resulting difference between the true isopycnic spacing and the final product (after editing) is presented in figure 5.2.5 and 5.2.6. Except for the top of the seasonal pycnocline, the error in isopycnic spacing in this model is close to the vertical resolution ( 12.5 cm ) . Nevertheless, in the region of strongest vertical gradients this error may exceed $20 \%$ of the true spacing for the case of non-uniform diving speed. Below this region the error in isopycnic spacing is less than $5 \%$. The accuracy of isopycnic spacing resulting from the mismatch in the time response of our sensors is $\varepsilon_{\Delta p}=0.2 \mathrm{~m}$.

This numerical study has also shown that a reduction of the errors in salinity requires a reduction of the diving rate, which should be constant over the total depth range. On the other hand, a reduction of the diving speed will result in a weaker slope of the fish track and the occurrence of density inversions due to internal waves is more likely.

The apparent thickness, caused by the slope of the internal waves compared to inclination of the fish track, will be increased, if the diving rate is reduced. Therefore one has to choose a compromise according to the scientific objectives of the data set.

### 5.3 Estimating the errors in the objectively analysed fields

As described above (section 4.10 ) the objective analysis is carried out using a tempered version of the autocorrelation function of the data to be analysed as the weighting function in the method of successive correction. The error field is calculated by considering the irregularly spaced input data which contributes to each grid point. Mathematically the objective analysis can be written as

$$
\begin{equation*}
\widehat{u}(\underset{\sim}{x})=\int_{s} w(\underset{\sim}{r}) u(\underset{\sim}{x}+r) d r \tag{5.3.1}
\end{equation*}
$$

where $u$ is the input data, $w$ the weighting function and $\hat{a}$ the objectively analysed field. Since the weighting function tends to zero within a finite
$\underset{\sim}{r}$ the area of integration $s$ is simply the area within which the weighting function is non-zero.

Equation 5.3.1 can be rewritten in the discrete form

$$
\begin{align*}
\hat{u}_{i j} & \left.=\frac{1}{n} \sum_{k=1}^{n} w_{i k}-x_{i j}\right) u_{k}  \tag{5.3.2}\\
\text { or } \quad \hat{u}_{i j} & =\frac{1}{n} \sum_{k=1}^{n} w_{k} u_{k} \tag{5.3.3}
\end{align*}
$$

for short, where $n$ data points contribute to the grid point ( $i, j$ ) and $w_{k}$ is taken to be the weighting appropriate to the position of $u_{k}$ relative to (i,j).

In order to describe the statistics of the data contributing to each grid point we have introduced two quantities, the weighted number of contributions (WNC) und the weighted root-mean-square error (WRMSE). These quantities are defined thus

$$
\begin{align*}
& W N C=\sum_{k=1}^{n}\left|w_{k}\right|  \tag{5.3.4}\\
& (\text { WRMSE })^{2}=\frac{1}{n} \sum_{k=1}^{n}\left[w_{k}\left(u-\widehat{u}_{i j}\right)\right]^{2} \tag{5.3.5}
\end{align*}
$$

The weighted number of contributions is therefore simply the sum of the magnitudes of the weights appropriate to such data points as are available to contribute to the grid-point in question. Since in the objective analysis, equation 5.3 .2 , data points only contribute according to their $w_{k}$ to the grid point field it was felt to be necessary to estimate in this way the number of contributions recelved by each grid point rather than consider the unweighted, integer number of data points contributing, which might be far away from the grid point and not influencing it aignificantly. In the case of the NOA' 81 data set, where the data were collected by a rather irregular survey pattern, it was particularly necessary to develop a criterion for distinguishing between those areas where sufficient data were available to be able to make a reliable objective analysis and those areas
where the data coverage was too low. It might reasonably be argued that a value of $W N C=1.0$ could be used to distinguish between well-measured and poorly-measured areas, since this value means that there is the equivalent of one data point contributing to each grid point. In figure 5.3.1 a map of the ship's track with the WNC field for temperature on sigma-t is shown.

In calculating the WRMSE it was likewise felt to be better to use the weighting function to modify the estimate of the fluctuations of the data relative to the grid points rather than use the unweighted variance of the data because the data points farther away from the grid point would naturally be expected to deviate further from the grid point value and in the sum of squares would dominate the calculation. The meaning of this quantity should be interpreted with caution however. Although we have loosely termed it an "error" it is not an inaccuracy in the same way as an instrumentation or calibration limitation. It should be seen as an estimate of that part of the spatial spectrum which cannot be represented on the chosen grid due to the, relatively, poor spectral window of the grid. Figure 5.3.2 shows $T)_{\sigma_{t}}$ and its WRMSE, figure 5.3.3.

Using the WNC and the WRMSE it was also possible to derive a weighted confidence limit (WCL) field using the well-known t-test formula (Kreyszig, 1968; Jenkins and Watts, 1968)

$$
\begin{equation*}
t_{v}\left(1-\frac{\alpha}{2}\right) \frac{\sigma}{\sqrt{n}} \tag{5.3.6}
\end{equation*}
$$

where $\sigma$ is the standard deviation of $n$ data points and $t_{v}\left(1-{ }_{2}^{\alpha}\right)$ is a factor depending on the number of degrees of freedom $\mathcal{X}=\mathrm{n}-1$ ). Our version of this formula is

$$
\begin{equation*}
\text { WCL }=t_{v}\left(1-\frac{\alpha}{2}\right) \cdot \text { WRMSE } /(\text { WNC })^{1 / 2} \tag{5.3.7}
\end{equation*}
$$

where the number of degrees of freedom $v$ is also taken to be WNC. For WNC less than unity WCL is not defined. The WCL for temperature on sigma-t is shown in figure 5.3.4.

### 5.4 Symopticity

The survey of the polar front took eight days and furthermore it was not conducted in a spatially systematic way. Little is known about the time scales of the synoptic and mesoscale turbulence in this area and due to the high cloudiness satellite images also fail to give the necessary information. It is however possible that the structures under observation were changing and developing during the period of the survey. In order to estimate the asynopticity for each part of the field, the time of the measurements was objectively analysed using the velocity component weighting functions and the statistics of the data points contributing to each grid point calculated as described in section 5.3. Within the area with WNC greater than 1.0 both the WRMSE and the WCL gave values of about 0.5 d . Thus the time scale for the lack of synopticity of the well-supported grid points was approximately half a day. This is probably shorter than the likely time scale of development of such meander structures in the ocean and therefore the lack of synoptic measurement and also the lack of systematic measurement would not seem to be too serious.

## 6. Standard products - offset profiles

As mentioned in the introduction only a subsample of the total data set will be presented here. These data were edited to stage 5 as shown in the flow diagram (fig. 4.1).

### 6.1 Profiles from the Long Sections

To give an impression of the variety of features along the 2500 km track, with approximately 5000 profiles, 5 sets of 21 successive profiles were chosen for more detailed presentation. The start and end positions of each set is listed in table 6.1. To present the location of the sets their numbers are marked in figure 7.1.6 showing the variability of temperature on constant $\sigma_{t}$ surfaces along the whole section.

Table 6.1: Location of 5 selected regions of long section B102

| Set <br> No. | Characteristic | Start |  | End |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Latitude N | Longitude W | Latitude N | Longitude W |
| 1 | horizontally homogeneous warm water | $40^{\circ} 38.58{ }^{\prime}$ | $28^{\circ} 6.36^{1}$ | $40^{\circ} 43.98{ }^{\prime}$ | $28^{\circ} 10.38^{\prime}$ |
| 2 | edge of an eddy | $42^{\circ} 23.59{ }^{\prime}$ | $29^{\circ} 28.01^{\prime \prime}$ | $42^{\circ} 28.50^{\prime}$ | $29^{\circ} 32.00^{\prime}$ |
| 3 | strong front | $47^{\circ} 52.50^{\prime}$ | $32^{\circ} 33.18^{\prime}$ | $47^{\circ} 56.64^{\prime}$ | $32^{\circ} 36.00^{\prime}$ |
| 4 | polar front | 51 ${ }^{\circ} 1.08^{\prime}$ | $34^{\circ} 28.08^{\prime}$ | $51^{\circ} 5.88^{\prime}$ | $34^{\circ} 31.80^{\prime}$ |
| 5 | homogeneous cold water | $53^{\circ} 6.54{ }^{\prime}$ | $35^{\circ} 50.52^{\prime}$ | $53^{\circ} 11.32^{\prime}$ | $35^{\circ} 53.10^{\prime}$ |

Figure 6.1 .1 shows profiles of set 1 in the warm water sphere (NACW) at $40^{\circ} 30^{\prime} \mathrm{N}$, belonging to a fairly uniform water mass.

Figure 6.1 .2 shows profiles of set 2 cutting a frontal structure at $42^{\circ} 20^{\prime} \mathrm{N}$. Especially in the salinity profiles it is apparent how the section crosses the front within 6 km . In this range colder lower salinity water is lying under the warmer water of profiles 100 to 112 .

Figure 6.1.3 shows a region where the section cuts a tongue of warm, saline water embedded in a colder surrounding. Below 40 m depth the boundary between the water masses is mach sharper than in the overlying water.

Set 4 is not presented here because the Polar Front is described in detail in section 6.2 .

Figure 6.1 .4 shows profiles of set 5 lying in the horizontally relatively uniform cold water north of the Polar Front.

### 6.2 Profiles from the Frontal Survey - sections C311 and C312

The following examples each show approximately $7-8 \mathrm{~km}$ of a typical region in the frontal area taken from sections "C311" and "C312" which were about 10 km apart. The start and end positions of these regions are listed in table 6.2. Each figure consists of twenty successive profiles of temperature, salinity and density. The even numbers by the profiles indicate that the profiles were taken from the descending sections of the fish track.

Table 6.2: Selected regions in sections C311, C312

| Section | Region | Start |  | End |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Latitude $\mathrm{N}$ | Longitude W | Latitude N | Longitude W |
| C311 | warm | $50^{\circ} 14.28^{\prime}$ | $34^{\circ} 59.70^{\prime}$ | $50^{\circ} 17.64^{\prime}$ | $35^{\circ} 2.94^{\prime}$ |
| C311 | front | $50^{\circ} 26.34^{\prime}$ | $35^{\circ} 13.14^{\prime}$ | $50^{\circ} 29.04^{\prime}$ | $35^{\circ} 17.70^{\prime}$ |
| C311 | cold | 50"37.98* | $35^{\circ} 37.20^{\prime}$ | $50^{\circ} 40.86^{\prime}$ | $35^{\circ} 42.12^{\prime}$ |
| c312 | warm | $50^{\circ} 19.38^{\prime}$ | $34^{\circ} 53.58^{\prime}$ | $50^{\circ} 21.72^{\prime}$ | $34^{\circ} 57.78^{\prime}$ |
| C312 | front | $50^{\circ} 30.06^{\prime}$ | $35^{\circ} 11.04^{\prime \prime}$ | $50^{\circ} 32.34^{\prime}$ | $35^{\circ} 15.54^{\prime}$ |
| C312 | cold | $50^{\circ} 42.96^{\prime}$ | $35^{\circ} 35.28^{\prime}$ | $50^{\circ} 44.40^{\prime}$ | $35^{\circ} 40.38^{\prime}$ |

These regions are presented in a set of offset profiles, they are marked in the section plots as "W", "F", "C" with a black bar (chapter 7.2); and they were also used (paragraph 7.1) for the average conditions in each of the areas.

The definition "warm" refers to the warmer part, "front" to the thermoclinicity maximum and "cold" to the colder part of the section in question.

Figures 6.2 .1 and 6.2 .2 were taken from the warm side, figure 6.2 .3 and 6.2.4 from the region of highest horizontal temperature gradient and figures 6.2 .5 and 6.2 .6 from the cold side of the front.

Plots of temperature versus $q_{t}$ reveal that thermohaline fine-structure was masked by the internal wave field. Again a set of figures (6.2.7-6.2.10) from both sides of the thermohaline front as well as the maximum gradient region is presented.

By comparing the profiles of temperature versus density the obvious difference in the three regions is the lack of fine-structure on the cold side, while the regions " $W$ " and " $F$ " show coherent temperature inversions over some kilometres with vertical scales of a few metres.

Offset-Profiles Section B102 at $40^{\circ} 41^{\prime} \mathrm{N}, 28^{\circ} 08^{\prime} \mathrm{W}, 5^{35 \mathrm{~h}}, 22.7 .81$ Temperature $\boldsymbol{1}^{\circ} \mathrm{C}$

## 7. STANDARD PRODUCTS - SECTIONS

### 7.1 Long Section

After processing stage 5 time series of values of temperature, sallnity, $\sigma_{t}$ and pressure measured at the upper and lower turning points of the towed fish give a comprehensive overview of the range reached by the instrument along a whole long section. They also reveal immediately a number of structures which can be analysed in detail in further analysis.

The pressure values at the upper and lower turning points (fig. 7.1.1) show that the fish scanned on average the water column between 5 m and 75 m . From the 24 th July the upper turning point was shifted to about 10 m due to bad weather conditions (fig. 10.1). A comparison with the mixed layer depth (fig. 7.1.2), determined by the sharp change of gradient of the temperature profile, shows that the fish always reached the "mixed layer" so that the upper turning point values represent the hydrographic conditions in the "mixed layer".

The temperatures of upper and lower turning points (fig. 7.1.3) show at first look similar patterns. However the surface temperatures show a somewhat smoother curve compared with the step-like variations at 75 m .

This difference between both curves is even more obvious in the salinities (fig. 7.1.4) where very sharp horizontal gradients underlie smoother gradients at the sea surface. Near the Azores saltier water is lying over fresher water at 75 m . Going north the surface salinfty decreases compared to the 75 -m-level, and stays consistently lower in the northern half of the section. The differences are notably larger around the main fronts.

The large-scale slope of the density distribution (fig. 7.1.5) shows the gyre-scale baroclinicity. The increased variability at the lower turning points between the $21 s t$ and 25 th July seems to be correlated with the changing wind during these days (figure 11.1).

According to the data processing flow diagram (figure 4.1 ) sections were plotted after interpolation onto constant intervals of either pressure or $\sigma_{t}$. The results of this processing stage are presented in form of contoured sections of the different variables with pressure or $\sigma_{t}$ as the vertical coordinates, and additionally as sections showing the horizontal distribution of a variable on a surface of constant density or pressure.

The presentation of temperature variations on equally spaced density surfaces avoids the distortion of the water column by internal waves. As temperature changes on an isopycnal must be compensated by salinity, they indicate water mass changes. Figure 7.1 .6 gives a comprehensive view of the horizontal as well as vertical water mass changes along the whole section.

Between $38^{\circ}$ and $46^{\circ} \mathrm{N}$ the water mass remains relatively uniform. Some synoptic-scale structures bounded by sharp fronts can be distinguished from large regions with length scales $40-300 \mathrm{~km}$ of uniform distribution.

From $46^{\circ}$ to $53^{\circ} \mathrm{N}$ temperature decreases stepwise. Only at a few sites the water mass changes are distributed continously over some tens of kilometres. At the majority of this extent narrow frontal regions of some kilometres width, perceptible by strong temperature steps and inversions are embedded in horizontally relatively homogeneons regimes.

The cold water region north of $53^{\circ} \mathrm{N}$ seems to have less horizontal water mass variability than the subtropical region.

The spacing between the isotherms indicates how much the stability of stratification is due to the temperature gradient. South of $45^{\circ} \mathrm{N}$ where a positive vertical salinity gradient (compare fig. 7.1.4) reduces the stability of the water column the spacing of isotherms is smaller than at $50^{\circ} \mathrm{N}$ or north of $53^{\circ} \mathrm{N}$ regions with stabilizing negative salinity gradient.

In frontal regions, where even temperature inversions are found, the much lower salinity of the overlying water keeps the stratification stable.

### 7.2 Frontal Survey

In order to show the large horizontal and vertical variability in the frontal area sections C311 and C312 were again chosen. From experience with the GATE Batfish data, Woods \& Minnett (1979) and Leach, Minnett and Woods (1985), it seems obvious to present the data in isopycnic coordinates, which should remove the strong internal wave signal. A set of standard isopycnals $\sigma_{t}=26.0 \mathrm{~kg} \mathrm{~m}^{-3}$ to $\sigma_{\mathrm{t}}=27.0 \mathrm{~kg} \mathrm{~m}^{-3}$ with $0.1 \mathrm{~kg} \mathrm{~m}{ }^{-3}$ increment was thought to be representative for that part of the seasonal thermocline which lies in the range of the towed fish. This also means, that there is almost no information about the "mixed layer". For a better comparison of the two sections, which originally have had reversed orientation, section C311 was reversed, and both sections were projected onto straight lines
defined by their start and end positions. Additionally the data were interpolated linearly to a standard horizontal spacing of $\Delta x=0.4 \mathrm{~km}$, which corresponds to the mean wavelength of the towed fish during the front experiment.

In figure 7.2 .1 the temperature on isopycnals is shown, and because the temperature will be compensated by salinity on any particular isopycnal, this parameter is an indicator of the water masses at the front. The most striking feature in both sections are the warm (salty) water at the southeast end and the cold (fresh) water at the northwest end, separated by a region of strong thermoclinicity, the temperature gradient on an isopycnal, which is only a few kilometres wide. Temperature inversions are observed in the warmer part of the sections, which is mostly dominated by salinity, whereas at the cold side, which is temperature dominated, almost no inversions occur.

Unfortunately in the case of the most important quantity for dynamical studies, namely the depth of the isopycnals, it is not possible to remove internal waves by such a simple method. Figure 7.2 .2 is therefore a mixture of the internal wave signal and frontal baroclinicity. Nevertheless both sections show similarities which are unlikely to be due to internal waves. So the upper isopycnals on the warm side are closer to the surface than on the cold side, which is in contrast to the large-scale baroclinfcity with the isopycnals sloping up to the cold (fresh) water in the north. This trend is reversed in the deeper part of the section, where $\sigma_{t}=27.0 \mathrm{~kg} \mathrm{~m}{ }^{-3}$ is found only in the cold and fresh region and is outside the fish's range in the warmer part.

Isopycnal spacing is presented in figure 7.2 .3 as the depth difference between successive isopycnals and $a=26.5 \mathrm{~kg} \mathrm{~m}^{-3}$. This should remove most of the internal wave signal, namely the lowest mode, which moves isopycnals up and down together. The higher modes, though less energetic, are still present. This plot should at least give an indication of the vortex stretching (Fischer, Leach and Woods, 1985). The maximum spacing above $\sigma_{t}=26.5 \mathrm{~kg} \mathrm{~m}^{-3}$ is found at about 50 km from the origin of the sections accompanied by a minimum below the reference surface. Strong similarities in the isopycnal spacing can be seen in both sections.

In order to illuminate the advantage of isopycnic analysis the temperature distribution on surfaces of constant pressure is also shown (figure 7.2.4). Here the standard surfaces were from 20 m to 80 m being 10 m apart. In this
diagram the "mixed layer" signal is present in the uppermost surface of 20 m , and the temperature distribution is due to internal waves as well as frontal structures. From the mean profiles in chapter 8 the magnitude of the internal wave contribution to the observed variability can be estimated.

In order to explore the vertical extent of the observed structures, a standard CTD section across the region of strongest thermohaline contrast was made. The station distance was 5 nautical miles and the CTD was lowered down to 600 m .

Figure 7.2 .5 shows the temperature distribution with strong horizontal gradients even in the deepest part of the section, although the strongest gradients were found in the top 200 metres.

Fig. 7.1.1: Pressure values at the upper and lower turning points of the towed fish's undulations along section B102.

Fig. 7.1.2: Mixed layer depth along section B102 defined by the criterion: the depth where the vertical temperature gradient exceeds $\frac{\mathrm{d} T}{\mathrm{dz}}=0.09 \mathrm{~K} \mathrm{~m}^{-1}$.

Fig. 7.1.3.-Fig. 7.1.5: Temperature, salinity and $\sigma_{t}$ at the upper and lower turning points of the towed fish's undulation along section B102.

Fig. 7.1.6: Temperature distribution on surfaces of constant $\sigma_{t}\left(\sigma_{t}=25.4\right.$ to $27.4 \mathrm{~kg} \mathrm{~m}^{-3}$ ) of section B102.
The numbered dots indicate the 5 selected sets presented as offset and mean profiles in chapter 6 .

Fig. 7.2.1: Temperature distribution on selected isopycnals ( $\sigma_{t}=26.0 \mathrm{~kg} \mathrm{~m}^{-3}$ $-27.0 \mathrm{~kg} \mathrm{~m}^{-3}$ ) of two parallel sections C311 and c312. Heavy bars indicate selected regions presented as offset profiles.

Fig. 7.2 .2 : Depth of selected isopycnals ( $\sigma_{t}=26.0 \mathrm{~kg} \mathrm{~m}^{-3}-27.0 \mathrm{~kg} \mathrm{~m} \mathrm{~m}^{-3}$ ) of two parallel sections C311 and C312. Heavy bars indicate selected regions presented as offset profiles.

Fig. 7.2.3: Depth of selected isopyenals relative to $\sigma_{t}=26.5 \mathrm{~kg} \mathrm{~m}{ }^{-3}$ for two parallel sections C311 and C312. Heavy bars indicate selected regions presented as offset profiles.

Fig. 7.2.4: Temperature distribution in seven depth layers, being 10 m apart from parallel sections c3ll and c312. Heavy bars indicate selected regions presented as offset profiles.

## 8. STATISTICS OF THE HYDROGRAPHIC DATA

In this chapter diagrams of mean profiles with their standard deviations will be shown. A comparison between data averaged on constant density with data averaged on constant pressure will be made, to show how much of the observed variability is due to internal waves and how much is due to frontal processes.

Histograms of salinity, temperature and normalized isopyenal spacing on surfaces of constant density are also shown.

T-S diagrams are presented to illustrate water mass characteristics.

### 8.1 Mean and standard deviation profiles

a) Frontal Survey

From the frontal area sections C311 and C3l2 are again shown. Mean profiles for the cold and warm side of the front are presented and can be compared with those from the region of maximum thermoclinicity. As In the series of offset profiles shown in paragraph 6.2 the averaging intervals were chosen to be 20 profiles ( $7-8 \mathrm{~km}$ ).

Figures 8.1 .1 and 8.1 .2 show mean profiles whith their standard deviations of temperature, salinity and density averaged on constant pressure. The statistical significance of these profiles can be seen from the number of contributions. The variability in these profiles is indicated by their standard deviations, being partly internal wave induced and partly due to the frontal variability. The variability is strongest at the thernoclinicity maximum and it is interesting to note that a well developed mixed layer can only be detected at the warm and cold side of the front.

In order to remove most of the internal wave signal figures 8.1.3 and 8.1.4 show the set of profiles averaged on constant $\sigma_{t}$. Notice the remarkable difference in the standard deviations of the 'front' compared with the other regimes, which means, that there is a very narrow $T-S$ relationship on both sides of the front with a highly variable transition zone in-between. As already mentioned the themohaline difference between these regions is increasing with depth.

For comparison of the internal wave-induced variability with that of the front, mean and standard deviation profiles of temperature and salinity
were averaged along constant $\sigma_{t}$, but plotted versus the mean pressure of the density layer in question (figures 8.1.5, 8.1.6). This procedure led to a reduction of the variability especially at the cold and warm sides.
b) Long Sections

Large-scale variability along section B102 can be seen from a series of mean profiles and their standard deviations of temperature and salinity (8.1.7., 8.1.8). Each of the profiles represent the average conditions for each degree of latitude, beginning just north of the Azores $38^{\circ} \mathrm{N}$ up to $55^{\circ}$ N. The averaging was performed on surfaces of constant ot to reduce the internal wave signal, but temperature and salinity are presented as a function of their mean pressures.

Most of the standard deviations of the averaged profiles are larger or smaller depending on the intensity of eddies and mesoscale fronts in the latitude interval. Only the averages centred at $46.5^{\circ}, 48.5^{\circ}, 50.5^{\circ}$ and $51.5^{\circ} \mathrm{N}$ which include the main branches of the Polar Front have clearly larger standard deviations and a different slope of the mean profile.

To show the clear differences of regimes regardless of their situation in geographical intervals, four of the selected sets described in paragraph 6.1 were averaged along isopycnals and presented versus pressure in figure 8.l. 10 analogous to the mean profiles of the frontal survey. The low standard deviations in the averages of set 1 and 5 indicate their situation in isopycnically homogeneous regimes. Set 1 situated in subtropical waters is thermally stronger stratified than set 5 lying in subpolar water. But the positive salinity gradient in set 1 reduces the stability, while the negative salinity gradient in set 5 supports the thermal stratification.

The large standard deviations of set 3 and 4 indicate the high horizontal variability in the regions of maximum thermoclinicity along the section. In both profiles they have maxima at about 30 and 50 m . The drastic decrease at the top of the profiles show how the strong thermoclinicity in the themociine is hidden from the surface by a horizontally much more horizontally homogeneous mixed layer.

A clearly distinguishable colder and fresher water mass in the upper 45 m leads to the bending of the mean profiles.

Section 8102 was averaged along constant densities in intervals of $1^{\circ}$ of latitude.

Statistical moments of the isopycnic distribution of pressure, temperature, salinity and the spacing between $\sigma_{t}= \pm 0.05 \mathrm{~kg} \mathrm{~m}{ }^{-3}$ are listed in tables 8.1.1-17 for isopycnals being $0.1 \mathrm{~kg} \mathrm{~m}^{-3}$ apart.

The uppermost value of any profile was excluded from averaging, to avoid the contamination of the statistics by values of the mixed layer. Unlike temperature and salinity where regions of relatively uniform water mass can clearly be distinguished from regions of varying water masses, the pressure distribution and the isopycnal spacing do not show obvious correlations with the hydrographic features.

The varlability of pressure is greatest near the Azores. In the frontal region it increases only in the lower layers at strong fronts. The spacing shows some isolated, heavily skewed distributions with high kurtosis.

## 8. 2 Probability distributions on surfaces of constant density

In this section probability distribution functions (PDF) of temperature (figure 8.2.1), salinity (figure 8.2.2) and pressure (figure 8.2.3) on surfaces of constant density will be shown. Each PDF represents all data points in the frontal region on a distinct $\sigma_{t}$-surface. The number of points In each window is normalized by the total number of points on that surface. The PDF's of salinity and temperature show a bimodal structure indicating the two water masses observed in that area. This bimodal structure is not observed in the pressure distribution, furthermore the pressure distribution is nearly Gaussian, espectally on the surfaces $\sigma_{t}=26.6 \mathrm{~kg} \mathrm{~m} \mathrm{~m}^{-3}$ and $\sigma_{t}=26.3 \mathrm{~kg} \mathrm{~m} \mathrm{~m}^{-3}$ where the kurtosis is around three (table 8.2 .1 ) and the skewness is very small. PDF's of normalized thickness (spacing between palrs of isopycnals being $0.1 \mathrm{~kg} \mathrm{~m}^{-3}$ apart) are also shown. To remove the effect of changes in the mean vertical density gradient, the thickness is normalized with regard to its mean value (see table 8.2.1). The resulting PDF's (figure 8.2.4) show a very skewed distribution, up to four times its mean value.

### 8.3 T-S Diagrams

a) Front Regions

One of the most classic diagrams in oceanography is that of the $T-S$ relationship, which again is presented for typical regions named " C ", "F", "W" from sections C311 and C312 (figure 8.3.1, 8.3.2.). The averaging was carried out along density surfaces and the bars in the figures denote standard deviations of typical places in the $T-S$ domain. The total range in salinity is $34.5 \cdot 10^{-3}-35.5 \cdot 10^{-3}$ and $9{ }^{\circ} \mathrm{C}$ to about $15{ }^{\circ} \mathrm{C}$. Comparing the T-S diagrams from "C" and "W" it can be seen that the salinities - as well as the temperatures - are closer to each other above $\sigma_{t}=26.0 \mathrm{~kg} \mathrm{~m}^{-3}$ and deviate more to about $\sigma_{t}=26.9 \mathrm{~kg} \mathrm{~m}^{-3}$, where the warm side shows a strong salinity maximum. This maximum could also be detected in the region of the thermoclinicity maximum. Furthermore the T-S profile in that region shows strong similarities to that of the warm side although the thermohaline variability, shown by the standard deviation bars is much stronger at the thermoclinicity maximum. Another notable feature is the very fresh water in the top layers of the thermoclinicity maximum region which can be explained by a phase shift of the thermoclinicity signal with depth and the very fresh band of water seen on the cold side of the thermoclinicity maximum in the section plots (figure 7.2.1).
b) Long Sections

The same presentation for the four typical sets of the long section B102 is used in figure 8.3.3. In the regions with relatively uniform water masses, No 1 and No 5 , where the standard deviation bars are small, the density stratification is mainly due to the positive temperature gradient. The salinity provides in region No 1 a slight reduction of the stability with its positive gradient and in region No 5 an increase in stability with a weak negative gradient. The two examples, chosen from regions with maximum horizontal temperature and salinity gradients show similarities, too. The upper part is mainly thermally stratified untll a clear increase of salinity indicates the transition to a different water mass in which the profile continues again in nearly vertical direction. The mixed layer represented by the uppermost standard deviation bar has a mach lower horizontal variability than the thermocline.

Table 8.2.1: Statistics of isopycnal surfaces averaged over the total frontal survey, NOA'81.

Fig. 8.1.1: Mean and standard deviation profiles for three selected regions; of section C311 averaged on surfaces of constant pressure.

Fig. 8.1.2: Hean and standard deviation profiles for three selected regions of section C312; averaged on surfaces of constant pressure.

Fig. 8.1.3:

Mean and standard
deviation profiles
for three selected
regions of section
C311; averaged on
surfaces of con-
stant density and
plotted versus $\sigma_{t}$.

Fig. 8.1.4:

Mean and standard deviation profiles for three selected regions of section C312; averaged on surfaces of constant density and plotted versus $\sigma_{\mathrm{t}}$.

Fig. 8.1.5: Mean and standard deviation proffles for three selected regions of section C311; averaged on surfaces of constant density and plotted versus the mean depth of the density surface in question.

Fig. 8.1.6: Mean and standard deviation profiles for three selected regions of section C312; averaged on surfaces of constant density and plotted versus the mean depth of the density surface in question.

## AVERAGED OFFSET - PROFILES

Fig. 8.1.7: Mean and standard deviation profiles of temperature averaged on constant $\alpha_{t}$-surfaces over $1^{\circ}$ of latitude along section B102 and plotted versus the wean pressure of the density surfaces.

Fig. 8.1.8: Mean and standard deviation profiles of salinity averaged on constant $\alpha_{t}$-surfaces over $1^{\circ}$ of latitude along section B102 and ploted versus the mean pressure of the density surfaces.

## AVERAGED OFFSET - PROFILES

Fig. 8.1.9: Mean profiles of averaged on constant $q_{t}$-surfaces over $1^{\circ}$ of latltude along section 8102 and plotted versus the mean pressure on the of surfaces.

Fig. 8.1.10: Mean and standard deviation profiles of temperature and salinity of selected sets no. $1,3,4,5$ on section B102 averaged on constant density surfaces and ploted versus the mean pressure on the $o_{t}$-surfaces.

Fig. 8.2.1: Histograms of temperature on three isopycnals from the frontal survey. The number of contributing data points in each class ( 0.2 K ) was normalized by the total number of data points on the surface in question.

PROBABILITY DENSITY

Fig. 8.2.2: Histograms of salinity on three isopycnals from the frontal survey. The number of contributing data points in each class ( $0.05 \times 10^{8}$ ) was normalized by the total number of data points on the surface in question.

PROBABILITY DENSITY

Fig. 8.2.3: Histograms of the depth of three selected isopycnals from the frontal survey ${ }_{4}$ The number of contributing data points in each class ( $2 \times 10 \mathrm{~Pa}$ ) was normalized by the total number of data points on the surface in question.

## PROBABILITY DENSITY

Fig. 8.2.4: Histograms of normalized spacing between isopycnals being $0.1 \mathrm{~kg} \mathrm{~m} \mathrm{~m}^{-3}$ apart and centred around the labelled isopycnal. The spacing was normalized by its ensemble mean. The number of contributing data points in each window ( 0.2 ) was normalized by the total number of data points on the surface in question.

Fig. 8.3.1 und 8.3.2: Mean T-S diagrams for selected regions of the parallel sections C311 and C312. The data were averaged on isopycnals and the standard deviation bars indicate the variablifty within each interval.

Fig. 8.3.3: Mean T-S diagrams of sets no. 1, 3, 4, 5 of section B102, averaged on isopycnals. The standard deviation bars indicate the variability at certain points in the profile.

## 9. ISOPYCNIC AND ISOBARIC MAPS FROM THE POLAR FRONT SURVEY

The data presented within this chapter were interpolated onto a regular $10 \mathrm{~km} \times 10 \mathrm{~km}$ grid by an objective interpolation procedure as described in section 4.10 . The interpolation onto the grid was carried out by using the weighting functions (figure 4.10 ), which were derived by smoothing the twodimensional raw autocorrelation function of the variable to be interpolated.

An isopycnic map of temperature on $\sigma_{t}=26.6 \mathrm{~kg} \mathrm{~m}^{-3}$ from the seasonal thermocline was already shown in chapter 5.4 together with the error fields (figures 5.4.1 - 5.4.4). For the same isopycnal the depth, i.e. the pressure distribution, is presented in figure 9.1, and the error fields figure 9.2 and 9.4 are calculated in the same way as for temperature. Although the pressure field is contaminated by internal waves, some similarities between the temperature field (internal wave-free) and the pressure field can be seen.

The large-scale trend, with the isopycnals sloping upwards to the north by about 10 m is reflected by the isopycnic depth in the cold tongue, compared with the depth in the warmer part of the meander structure (see also figure 5.3.2). The general north-south trend is distorted by a meander structure of about 200 km wavelength with a region of sharp themohaline contrast between its troughs. Within the high resolution area between $36^{\circ} \mathrm{W}$ and $35^{\circ} \mathrm{W}$ the isolated temperature island (less than $11{ }^{\circ} \mathrm{C}$ ) 1 s correlated with a depth maximum, which is contradictory to the general trend (cold $=$ shallow).

Spacing between isopycnals $26.55 \mathrm{~kg} \mathrm{~m}^{-3}$ and $26.65 \mathrm{~kg} \mathrm{~m} \mathrm{~m}^{-3}$ is shown in figures 9.5 to 9.8 as the deviation from the mean spacing. This parameter can be understood as one component of the isopyenic potential vorticity (Fischer, Leach and Woods, 1985). This field is thought to be almost internal wave-free, because most of the internal wave energy is concentrated in the lowest wavenumber, which will move the isopycnals up and down together (Leach, Minnett \& Woods, 1985). Only the high wavenumber part of the internal wave field will contaminate this signal.

In order to show the structures within the mixed layer, which is not possible by isopycnic analysis, isobaric maps of the salinity and temperature field at 20 mare shown in figures 9.9 and 9.10 .

It is possible to create maps for any level within the interval 15 m to 80 m Wh a vertical separation of 1 m . For the isopyenic maps the interval is of $=25.9 \mathrm{~kg} \mathrm{~m}^{-3}$ to ot $=26.9 \mathrm{~kg} \mathbb{m}^{-3}$ with an increment of $0.025 \mathrm{~kg} \mathrm{~m} \mathrm{~m}^{-3}$.

NOA ' 81

Fig. 9.1: Objectively analysed depth of isopycnal of $=26.6 \mathrm{~kg} \mathrm{~m}^{-3}$ at the Polar Front. Grid dimensions were $10 \mathrm{~km} \times 10 \mathrm{~km}$.

Fig. 9.2: Weighted number of contributions of the depth of $\sigma_{t}=26.6 \mathrm{~kg} \mathrm{~m}^{-3}$. Grid dimensions were $10 \mathrm{~km} \times 10 \mathrm{~km}$.

Fig. 9.3: Weighted RMS-error of the depth of $\sigma_{t}=26.6 \mathrm{~kg} \mathrm{~m} \mathrm{~m}^{-3}$. Grid dimensions were $10 \mathrm{~km} \times 10 \mathrm{~km}$.

## 10. SURFACE CURRENTS

### 10.1 Data Acquisition

Throughout the Sea Rover legs of the "Poseidon" NOA '81 cruise the flow of water at the sea surface was estimated using the difference of the motion of the ship relative to the sea floor and relative to the water. The absolute motion of the ship was determined using satellite navigation, which gave the absolute position of the ship at irregular intervals ranging between about one and three hours. The motion of the ship relative to the water was obtained by integrating the signal from a two-component electromagnetic log mounted below the ship's well. The integration of the signal from the log was carried out using the ship's HP 1000 navigation computer, to which the $\log$ was interfaced. The $\log$ was calibrated off the Azores on 18 July 1981 using a drifting radar-buoy with a sail centred at the depth of the log. The two components were calibrated separately. The calibration and integration took account of mis-alignment of the head of the log. Further details of the navigation system and the calibration procedure are contained in Leach, 1984.

The position of the ship at times of the satellite fixes and the corresponding relative positions were extracted from the 2 -minute protocol printed by the navigation system. These were then typed into the HP9825A desk calculator. The difference in the change of absolute position of the ship between two satellite fixes and change of position relative to the water during the same period was then calculated and divided by the time interval giving the mean surface current for the space and time interval. This was assigned to the mean absolute position of the ship during the interval.

### 10.2 Derivation of the streamfunction in the synoptic-scale survey area

Within the box $38^{\circ} \mathrm{W}-30^{\circ} \mathrm{W}$ and $50^{\circ} \mathrm{N}-52^{\circ} \mathrm{N}$, see figure 11.1 , there were 137 satellite fixes between which 136 mean surface current vectors could be calculated. The mean surface veloctity is $0.08 \mathrm{~mm}^{-1}$ to the eastnortheast $\left(72^{\circ}\right)$ and the rms speed is $0.3 \mathrm{~m} \mathrm{~s}^{-1}$, while the maximum velocities associated with the core of the jet stream sometimes exceed $1 \mathrm{~m} \mathrm{~s}^{-1}$, as can be seen in figure 10.2 .1.

Visual comparison of the current vectors with the thermohaline structures (figures $10.2 .1,5.4 .2$ ) shows that at least in places the current appears
to be flowing quasi-parallel to the isolines of say temperature on density surfaces. This result was sufficient to encourage us to try and obtain a streamfunction which could more easily be compared with the thermohaline structures. After consideration of methods suggested in the literature (see Bretherton et al., 1976, for example) it was decided to try another method as follows. The east ( $u$ ) and north ( $v$ ) components of the current were interpolated separately onto a regular grid with 10 km spacing using their auto-correlation functions as weighting functions (figure 10.2.2).

The vorticity field was calculated from the grid point $u$ and $v$ fields (figure 10.2 .3 ), using a central difference scheme. The general feature of this quantity is a banded structure along the axis of the jet, symptomatic of the crossjet shear and with extreme values in the regions of strongest curvature of the flow field. Comparison with the planetary vorticity $f$ shows, that the relative vorticity is of the same order of magnitude, with maximum cyclonic relative vorticity of about $60 \%$ and maximum anticycionic vorticity of about $70 \%$. Furthermore the restriction of the estimates of the surface current to one per satellite fix restricts the observable vorticity to about $\pm 100 \mathrm{M} \mathrm{s}^{-1}$ (when the maximum currents seen of about $1 \mathrm{~m}^{-1}$ are observed with a spacing of some 20 km say). The rms vorticity of the analysed field is $11.6 \mathrm{M} \mathrm{s}^{-1}$ or about $10.4 \%$ of f . The ratio of the relative vorticity to the planetary vorticity can be interpreted as a Rossby number (Ro $m \frac{5}{f}$ ) and the large value of this quantity draws attention to the fact, that in regions such as this it is no longer advisable to regard the flow as quasi-geostrophic.

The vorticity field was then integrated using the technique of successive over-relaxation to solve the Poisson equation for the streamfunction. From the $u$ and $v$ fields the gradient, Dirichlet, boundary conditions were available for the integration. The resulting streamfunction shown in figure 10.2.4 bears comparison with the hydrographic structure shown in figure 5.4.2. Both show southward meanders at $35^{\circ} 30^{\circ} \mathrm{W}$ and $33^{\circ} 0^{\circ} \mathrm{W}$ and a northward meander at $34^{\circ} 30^{\circ} \mathrm{W}$. The general structure of the streamfunction shows a smoother appearance than the temperature field, which may to some extent be due to the analysis technique acting as a filter. It is interesting to note, that the width of the jet between the trough and the ridge is nearly twice that of the thermoclinicity maximum.

By differentiating the streamfunction it is possible to obtaln a geostrophic velocity field. This is shown in figure 10.2 .5 .

Further discussion of the dynamic quantities at the Polar Front is to be found in Fischer, Leach and Woods (1985) and detailed discussion of the analysis of the current data in Leach (1985).

## 11. METEOROLOGICAL DATA

During the NOA'81 expedition two independent automatic systems for measuring meteorological parameters were installed on "Poseidon". The Tefrimet (designed by Fa. Theodor Friedrichs) system recorded dry bulb, wet bulb and sea surface temperatures, wind speed and direction and air pressure with a time interval of one minute.

The new equipment built from a design by Dr. K. Uhlig, Department of Maritime Meteorology, IfM-Kiel, still in the test phase, had the advantage of recording mean values averaged over a predetermined interval. It had two sensors for dry and wet bulb temperatures and one sensor each for wind speed and direction as well as short-wave downward radiation.

Both data sets had large gaps. Therefore the presentation here (fig. 11.1 - 11.3 ) is the best possible combination of data from both systems.

The wind data are only recorded and displayed relative to the ship's speed and heading.

Figure 11.1 presents the meteorological data during the long section B102. In the first 3 days of the long section FS "Poseidon" steamed through the region of the Azores high pressure area with few clouds, relatively dry air and low winds. Steaming through the anticyclone the ship passed through regions of easterly, southerly and westerly winds. On the 23 rd July the ship came into the influence of stronger westerly winds, advecting more humid subpolar air. Passing fronts provided complete cloud cover.

Figure 11.2 presents the meteorology measured on the long legs of the front survey. The first two days the centre of an anticyclone with a central pressure of 1035 hPa was situated 400 km south of the survey region. Due to it the ship operated under cloudless sky, in dry air and southwesterly wind. On the 29 th July an occluded front system attached to a cyclone with central pressure of $995 \mathrm{~h} p \mathrm{a}$ passed over the survey region. The wind increased to $20 \mathrm{~ms}^{-1}$ from a southwesterly direction and advected air, which although $2^{\circ} \mathrm{C}$ warmer than the local sea surface temperature was highly saturated with water vapour.

During the high resolution part of the front survey the cyclone intensified till the 2 nd August to a central pressure of 975 hPa . Its centre was situated 900 miles north of the survey region (figure 11.3).

During the last two days the wind decreased but still advected polar air colder than the sea surface temperature on the cold side of the front. Due to a stationary front the area was covered with stratus clouds.

Fig. 11.2: Wet and dry bulb air temperature, wind speed and direction, air pressure and short wave irradiance during the synoptic scale part of the frontal survey.

Fig. 11.3: Wet and dry bulb air temperature, wind speed and direction, air pressure and short wave irradiance during the high resolution part of the frontal survey.

## 12. CONCLUSIONS

The experiment NOA' 81 was the first of a series of experiments carried out with our new measurement system, called SEA ROVER.

The SEA ROVER is an integrated system measuring hydrography and currents In the upper boundary layer of the ocean, combined with meteorological measurements, navigation and real-time data processing, from the moving ship, steaming at almost full speed.

We were able to monitor large areas with higher horizontal resolution in shorter time than classical CTD surveys, the cost being the limited depth range and the relatively large technical expense. Real-time data processing allowed a spontaneous adjustment of the survey pattern according to the just measured hydrographic situation. New problems in calibration, timeconstant behaviour and temperature dependence of the sensors were caused by high diving speeds of the fish. The applied scheme of recalibration, editing and data reduction succeeded in correcting some of the errors in the measurements. The accuracy was sufficient to resolve the strong signals in the upper boundary layer. In later experiments (NOA'83) the diving speed of the fish was reduced in order to avoid some of the detected error sources.

The NOA'81 experiment provided a data set of hydrography in the upper 80 m , surface currents and meteorology continuously measured over a distance of 12 Mm . The high horizontal resolution over long sections span up a spectral range of $0.4-2500 \mathrm{~km}$, the towing speed of 10 knots improved the synopticity of the measurements, and the data rate of 16 cycles per second raise statistical significance. Repeated surveys of the same track on return trips allow to investigate temporal changes.

With the use of isopycnic analysis we were able to discriminate oceanic finestructure from internal waves. For example the presentation of temperature on surfaces of constant $\sigma$ show clearly the extension of different water masses and thus eddies, meanders, tongues and fronts are detectable.

Averaging over a large number of data samples improved the signal to noise ratio and increased the statistical significance. These statistical results can be used for the test of models or the comparison with climatologeial data.

The high horizontal resolution reveals new insights in the large-scale structure of long sections intersecting the streamlines of the subtropical
gyre. Large regions of relatively homogeneous T -S relationship alternate with narrow bands of strong horizontal gradients. The transition zone between the subtropical warm water and the subarctic water extends over 700 km . The transitions themselves are found mainly at four strong fronts not broader than 50 km each. The intermediate regions only show mesoscale variability like the waters near the Azores or north of the Polar Front. The horizontal patterns differ also vertically. While water mass changes in the seasonal thermocline occur nearly steplike, horizontal gradients in the mixed layer are minh weaker and often are phase-shifted compared to the structure in the thermocline. Thus the mixed layer masks the pattern of the underlying water, a result which may be important for remote sensing. At the Polar Front between $50^{\circ} \mathrm{N}$ and $52^{\circ} \mathrm{N}$ synoptic-scale meanders with wave-lengths of about 200 km have been observed. The structures detected in the hydrographic data show strong similarities with the surface currents on scales larger than 20 km . The lack of horizontal resolution in the navigation data hindered us from comparing hydrogaphy and current measurements on smaller scales. Improvement of the navigation system is therefore necessary for the investigation of structures like the thermoclinicity maximum which was less than 10 km wide.
