Zusammenfassung

Wachstum der zunächst bestandsbildenden Nano- und Picophytoplankter wurde nicht in Form messbar erhöhter Sinkstoffraten umgesetzt. Die später im Experiment stattfindende Blüte weitaus größerer Diatomeen führte sofort zu ansteigenden Sinkstoffflüssen. Das durch die vorausgehende Blüte bedingte Defizit an anorganischen Nährstoffen führte unter erhöhter CO₂ Konzentration jedoch zu vermindelter Produktion von Diatomeen, welche womöglich selbst relativ unbeeinflusst von CO₂ wachsen.

Summary

This thesis deals with the optimisation of a marine pelagic mesocosm set-up for quantitative measurement of biogeochemical fluxes of matter within plankton ecosystems. The KOSMOS (Kiel Off-Shore Mesocosms for future Ocean Simulation) mesocosms are cylindrical transparent plastic bags designed to enclose representative samples of the naturally occurring plankton food web. Nine independent, rugged flotation frames support the 20 to 25 m deep watertight bags - depending on the specific experiment set-up - thereby covering the most productive part of the surface water layer. The data presented in this thesis were recorded in the context of an experiment designed to examine the effects of a projected future anthropogenic rise of aquatic CO₂ concentrations. This rise was simulated through graded addition of CO₂ across nine mesocosms. The objective was to trace natural carbon fluxes from the atmosphere into plankton biomass and via sinking of particles into deeper water layers. Changes in this biological carbon transport caused by increased CO₂ concentrations could have far-reaching consequences for the ocean in its function to naturally absorb large parts of the anthropogenic carbon emissions. Measuring the development of full budgets of carbon, nitrogen, phosphorus and silica over time in mesocosms of this size is unprecedented and could provide valuable quantitative data connecting ecology to biogeochemistry.

In a short introduction, an outline of the mesocosm approach as well as implementation options with particular regard to pelagic fluxes will be presented on the basis of examples. Three technical publications and a publication discussing measured carbon fluxes and budgets in the Svalbard 2010 ocean acidification study constitute the body of the thesis. The first technical note describes the mesocosm set-up; while the second manuscript deals with the measurement of the enclosed water volume in flexible wall mesocosms. A technique for tracer-based estimates of gas exchange with the atmosphere is described in a third technical publication. A precise knowledge of gas exchange rates is not only a prerequisite for carbon budgeting, but also relevant for issues concerning marine production of climate relevant trace gases. These publications on mesocosm methodology are followed by a so far unpublished description of a technology for quantitative measurement of sediment samples, developed for KOSMOS. In the first experiment using the described tools, some insights into the role of ecology for biogeochemical fluxes of matter through the plankton food web and into deeper water layers have already been gained. A significant beneficial influence of increased CO₂ concentrations on the growth of pico- and nanophytoplankton was not translated into measurably increased sedimentation rates. At a later point in the experiment, the flourishing of much larger diatoms immediately resulted in increased sedimentation rates at low CO₂ concentration levels. However, under conditions of increased
Summary

CO₂ concentrations, the deficit of inorganic nutrients, caused by the preceding pico- and nanophytoplankton, reduced the production of diatoms, whose growth is presumably relatively unaffected by CO₂ levels.

For all the important findings, there is still room for improvement of the experimental set-up. Therefore, a description of the most important technical improvements realised as a result of the 2010 experiment is enclosed. In the section entitled “Perspectives”, some thoughts on the improvement of data collection and analyses as well as promising experimental concepts and implementation options with regard to tropical upwelling events are presented.
1. Introduction

1.1 Mesocosms

A mesocosm is an experimental enclosure containing more than two interacting species forming an ecosystem (Odum, 1984). The word “mesocosm” originates from the ancient Greek language and refers to the scale of a system. As a compromise between “cosmos” - the universe - and “microcosmos” - a small subunit of the universe - mesocosm describes a setup for controlled ecological experiments mimicking the field. From spatially defined field areas, through cages, to chemically isolated laboratory chemostats, the range of implementations of this concept seems endless (see book: “Enclosed Experimental Ecosystems” 2009). The common objective of mesocosm approaches is to provide experimental data on ecology within enclosed systems. Results of mesocosm experiments can form a basis for the extrapolation of physiological data on ecosystem components to natural communities observed in the field. As exchange of resources and biomass are restricted, transformations of matter become quantitatively traceable. Repeated sampling of precisely the same body of water is nearly impossible in aquatic field work, for oceanographers even more than for limnologists. Approaches to follow and re-sample ocean water masses using lagrangian drifters and chemical tracers (e.g. Landry et al., 2009; Bakker et al., 2005) are limited in time to a few days. Temporal succession within a series of field measurements can, due to mixing processes, never be as quantitatively precise as within a closed system. Important hints for understanding key processes like primary production in the sea (McAllister et al., 1961), benthic-pelagic coupling (Smetacek et al., 1976) or the formation of fast sinking marine aggregates (Alldredge et al., 1995) could thus already be achieved by following the succession of a plankton community over time in one single mesocosm. The effect of physical or chemical influences on community succession can be tested in perturbation experiments by using a set of replicated mesocosms. Recommendations for experimental design of pelagic mesocosm CO₂ perturbation studies are given in Riebesell et al. (2010).

Mesocosm experiments always represent a compromise between reality observed in the field and control and reproducibility achieved under laboratory conditions. Set-ups very close to the natural system might encounter a high level of variability and a large number of insufficiently determined variables, making obtained data in the end too complex to draw conclusions on many processes of interest. Highly controlled set-ups, on the other hand, premise a strong reduction of complexity and natural variability so that extrapolation of the described relationships to the natural system becomes questionable.
Observing natural communities in enclosures can be realised by simple means, however, the optimisation of a setup towards maximum realism at maximum control can become technically complex.

1.2 Elemental budgets in plankton mesocosm research – a historical review

Pelagic mesocosms have been an established tool in marine plankton research for more than 50 years (Strickland et al., 1969). Nevertheless, no standard protocols for mesocosm studies exist, nor even a common design of the enclosure. The diversity of shapes and sizes of in situ pelagic mesocosms similar to the enclosures being subject of this thesis is illustrated in Fig. 1.2. Beyond a well-reasoned choice of scale, all those designs are fitted to the specific type of question to be answered. Even more important in marine environments, however, is to construct a mesocosm that is durable enough to brave the elements for the duration of the planned experiment. For the following short review several designs of pelagic mesocosms were chosen, in size, research approach, or structure more or less directly comparable to the KOSMOS mesocosms.

![Figure 1.2. Examples for various enclosure designs used as marine plankton mesocosms. All chosen examples are designed for research from plankton ecology to biogeochemical fluxes. a) "Large plastic bag" (113\(m^3\)) by Strickland and Terhune (1961). b) Seamless plastic tubes (4-40\(m^3\)) described by Brockmann (1992), shown in the free drifting flotation frame with bags of different length. c) Loch ewe enclosure (~100\(m^3\)) by Gamble et al. (1977). d) 0.25 CEE (~68\(m^3\)) and e) full size CEE (~1700\(m^3\)) as described by Menzel and Case (1977). f) KOSMOS (~50-80\(m^3\)) as described by Riebesell et al. (2013).]
First reported results from marine plastic bag enclosures by Strickland and Terhune (1961) (1, 2a) were published by McAllister et al. (1961) and Antia et al. (1963). One spherical bag equipped with a steering mechanism and pneumatic buoyancy compensation was filled with filtered seawater and inoculated with a natural phytoplankton community. Measurements of phytoplankton community composition and biogeochemical parameters were supplemented by a set of primary production estimates. In situ $^{14}$C uptake, oxygen production, pH change as well as particulate organic carbon and cell production were in good agreement within this well stirred gas-tight bag (Fig. 1.3). The experiments gave a first impression of community primary production and dynamics of elemental composition of particles in the sea.

Around ten years later, the mesocosm initiative CEPEX (Controlled Ecosystem Pollution Experiments) initiated parallel development of mesocosms around the world. Within the centre of investigation were questions concerning ecological effects and residence time of contaminants like heavy metals and crude oil within coastal waters. The Scotch Loch Ewe mesocosms (Fig. 1.2c; Gamble et al., 1977) were similar to the Strickland model tapered to the surface but, cylindrical in shape, they had the advantage of a linear representation of the light gradient within the euphotic zone. Instead of homogeneous mixing, a funnel-shaped bottom with a collecting cup for sediment sampling by scuba divers was attached. Full natural plankton communities were investigated including the simultaneous rearing of cod and herring larvae as well as lobster inside the mesocosms. Budget calculations were performed in one of the first experimental trials (Gamble et al., 1977). Due to obvious leakage of most of the bags, rough budgets were only calculated for nitrogen in the least corrupted bag. Around 4% more N than added was found after
55 days of daily fertilisation. This result was surprising, as strong wall growth, mentioned several times within the manuscript, should have absorbed large amounts of nutrients.

In Germany, several types of mesocosms were developed between 1970 and 1990. Among those, the seamless polyethylene bags of Brockmann (1992) represented the most productive concept. Simple bulk stock 1 m diameter plastic sleeve was used in combination with various flotation devices. Several years of research within Heligoland harbour focussed on the production and consumption of dissolved organic substances as well as ecological consequences of pollution. The three-bag conuration as shown in Fig. 1.2b was designed to perform drifting experiments within the North Sea. The POSER (Plankton Observation with Simultaneous Enclosures in Rosfjorden) project (Brockmann et al., 1983) used these seamless plastic tubes to compare results from bags of various dimensions. Elemental budgets could not be constructed because sinking material was neither extracted nor kept in suspension. Therefore, accumulation and remineralisation of material at the bottom of the enclosure represent an unknown exchange process. The Canadian CEE (Controled Ecosystem Enclosures) mesocosms (Fig. 1.2d, e; Menzel and Case, 1977) were certainly the most impressive structures in the history of marine pelagic mesocosms. KOSMOS resembles CEE in many details; open top cylindrical bags with a bottom funnel forming a sediment trap that can be emptied through an extraction tube to the surface. CEEs were equipped with two to three layers of foil and Dacron to prevent failures due to bag damage, a permanent threat to flexible wall mesocosms. Absorption of large parts of the natural turbulence by these rather rigid walls was held responsible for falling out of larger phytoplankton in the beginning of the experiments (von Brockel, 1982). A test version of the CEE, 25% of the original size, (Fig. 1.2d) was used for most studies due to the high costs and difficult handling of full size CEEs. One of the more elaborated nitrogen budgets within the 25% CEEs was published by Harrison et al. (1977). Calculations were based on nitrate additions, as well as measurements of particulate organic and dissolved inorganic nitrogen. Assuming a single pathway of nitrogen flow (inorganic N to particulate N to sediment), sedimentation was calculated by mass balance. Calculated sedimentation, that was sampled but could obviously not be measured, strongly resembled nitrate additions to the mesocosm. It was concluded that nitrogen export is a function of nitrogen input. Results merely document that nitrate added on a regular basis did not accumulate in the water column or in particles therein. Accumulation of dissolved organic nitrogen or wall growth featuring possible alternative nitrogen pools other than sediments were not discussed. Daily removed settled material was, also in later budget approaches (e.g. Hattori et al., 1980; Vadstein et al., 2012), at best qualitatively analysed. Examples where direct quantitative measurements of settled material were used for mesocosm
Introduction

budget calculations could not be found. Reasons for the often problematic quantitative analyses of dense sediment samples are discussed in Section 2.4.

In a critical review article, Banse (1982) indicated the general shortage of studies evaluating elemental budgets. This critical point was picked up in a review by Brockmann (1990) who attributed it to a lack of interdisciplinary expertise needed to determine all the parameters within the same experiment. Still, substantial amounts of useful data, which could not be obtained by other means, were produced using mesocosms. Not only were the effects of pollutants on plankton ecology and production described, but important interactions within the planktonic food web in general could be quantified (Lalli, 1990). As one of the overall results, it was found that enclosed ecosystems reacted often far more sensitively to chemical perturbations than could be expected from single species lab experiments (Kuiper, 1982). Those responses are often initiated by shifts in species composition, which cannot be realistically represented within lab experiments on one or few species. Most mesocosm experiments since the 1980s focussed on ecological and biogeochemical interactions within parts of the enclosed ecosystem rather than on full elemental budgets. An overview of currently operating mesocosm facilities and their research focus is given on the homepage of MESOAQUA (mesocosm.eu). Some facilities have a long tradition in flexible bag mesocosm experiments; the Bergen-Espegrend mesocosm facility is performing experiments on a regular basis since 1978. Recently the impact of atmospheric dust deposition on carbon export in the oligotrophic Mediterranean was investigated using the “large clean mesocosms” (Guieu et al., 2013). The influence of dust ballast on aggregate formation and sinking was described by sediment carbon measurements as well as in situ optical instruments without applying a carbon budget approach. A clear correlation of dust input to export was shown, but the origin of the carbon exported from the mesocosms remains unclear (Bressac et al., 2013). A comprehensive experiment focussing on ecosystem carbon and nutrient flows using seven 40m$^3$ mesocosm bags was performed in Hopavågen lagoon close to Trondheim/Norway in 1997 (Vadstein et al., 2012; Olsen et al., 2007). Although many components of the carbon budget (e.g. inorganic carbon, sedimentation and gas exchange) were not directly measured, plausible elemental fluxes and budgets could be determined by mass balance and measured stoichiometry. Inverse modeling was combined with differential measurement of particulate matter and metabolic rates within four size fractions. A sophisticated sampling protocol harmonized with modeling allowed for presentation of plenty of metabolic rates that can, in parts, impossibly be measured directly in a natural system (see flow network Fig. 1.4).
Introduction

Figure 1.4. Flow network for inverse mesocosm ecosystem modeling from Vadstein et al. (2012) is fitted to a size fractionated data acquisition protocol. Abbreviations: DIC-dissolved inorganic carbon, DOC-dissolved organic carbon, DIN / DIP-dissolved inorganic nitrogen / phosphorus, DON / DOP-dissolved organic nitrogen / phosphorus, DeN / DeP / DeC-detritus nitrogen / phosphorus / carbon, SeN / SeP / SeC-sediment nitrogen / phosphorus / carbon, COP-copepods, CIL-ciliates, BAC-bacteria.

Whether more complete data coverage, also reducing the number of adjustable variables, would have increased capabilities of the model remains questionable. Measurement of carbon budgets, however, was not performed within large mesocosms until recently, when the transport of man-made atmospheric CO₂ by the biological carbon pump became a relevant research question. For the first time inorganic carbon concentrations were measured in large marine ecosystem experiments. Carbon mass balance calculations for experiments in shallow mesocosm bags in Bergen-Espegrend were used to draw conclusions on carbon export at future CO₂ levels (reviewed in Riebesell et al., 2008). Increased carbon loss from the budget at high CO₂ concentrations was thought to originate from polymerisation of exudates from CO₂ fertilised phytoplankton, leading to a measured increase in carbon content of the sedimenting material (Delille et al., 2005). This promising Bergen carbon budget approach would have profited from quantitative sediment sampling, as well as from data-based estimates for air-sea gas exchange. These first ocean acidification plankton mesocosm experiments acted as an impulse for the development of the methodology presented in this thesis.

1.3 The choice of scale

Scale is an integral feature in the definition of a mesocosm, representing a unit larger than a microcosm but smaller than a whole biotope. Depending on the size, behaviour, and generation
time of organisms studied, mesocosm experiments need appropriate spatial, structural and temporal dimensions in order to produce data applicable to the natural system (Petersen et al., 1999). Improving realism of experimental ecosystems can be achieved by increasing size and complexity. This is not only restricted by technical and financial limits, but also by the effort needed to gain sufficient data for description of the system.

Plankton communities in pelagic mesocosms are mainly composed of relatively small organisms with relatively short generation times (days to months). Additionally, the pelagial seems to be homogeneous and more or less unstructured compared to terrestrial or benthic habitats. Accordingly, it should be principally easy to enclose a relatively complete plankton ecosystem for a sufficient period to observe ecological and biogeochemical processes under realistic conditions. Yet, a closer second look shows that this is only partly true. The enclosure itself, necessarily a rigid structure, constitutes a major perturbation to the pelagic system. The walls of the mesocosm provide habitat for benthic species that compete with plankton (Chen et al., 1997). Inner walls of previous flexible wall mesocosms could generally not be cleaned. This procedure, which is standard for many rigid land-based mesocosms (see book: “Enclosed Experimental Ecosystems”, 2009), is a basic prerequisite for budget calculations with an experimental duration of several weeks. Small-scale turbulence and large-scale convection, structuring the natural habitat of planktonic organisms, are significantly changed compared to open waters due to energy dissipation by the walls (von Bröckel, 1982). Especially in shallow set-ups, turbulence has to be deliberately generated to keep cells in suspension (reviewed by Sanford, 1997). The most efficient way of reducing wall artefacts is again by increasing the volume of the enclosure to decrease relative wall surface.

![Box plots of mesocosm volume versus replicates per treatment and number of treatments.](image)

**Figure 1.5.** Box plots of mesocosm volume versus a) replicates per treatment b) and number of treatments. Data are sampled of 266 published papers on aquatic mesocosm research. Median values are represented by the bar within the box and the interquartile range by the top and bottom of the box. Whiskers represent data range within 1.5 times the interquartile, data outside this range are marked by asterisks. Plot modified from Petersen et al. (1999).
Due to increased costs and effort at increased size, the number of replicates is inversely related to mesocosm size, with negative effect on confidence in the findings (Petersen et al., 1999). MEERC (Multiscale Experimental Ecosystem Research Centre) invested more than a decade to test scale-related theory, to improve experimental design and to develop rules and tools for extrapolation from experiments to nature. Results mainly achieved within land-based pelagic, benthic as well as salt marsh ecosystem enclosures are summarised in the Book “Enclosed Experimental Ecosystems and Scale: Tools for Understanding and Managing Coastal Ecosystems” (2009).

Besides turbulence, another structural feature relevant for deep pelagic mesocosm systems is horizontal stratification. Density gradients depict horizontal borders to the pelagic communities in the water column, mostly connected to chemical and physical gradients of the stratified water body. The upper mixed surface layer encounters the euphotic zone, where light is sufficiently available for photosynthetic primary production. Covering the entire euphotic zone with a pelagic mesocosm experiment enables estimating ocean primary production. While it is technically feasible to cover more than the eutrophic zone with less than 20 m long bags in turbid productive waters, the extension of the entire euphotic zone is usually beyond the reach of mesocosm instrumentation in oligotrophic waters. Theoretical considerations for the design of CEE in-situ pelagic mesocosms considered 1.3 times the depth of the euphotic zone as an optimal extension of an experimental unit (Menzel and Case, 1977). The design culminated in the construction of 29 m deep and 10 m wide mesocosms with a volume of 1700 m$^3$ (Fig. 1.2e).

Additionally to vertical gradients also found in more narrow tubes, significant horizontal inhomogeneity was observed at 10 m diameter (Takahashi et al., 1975; Grice et al., 1977). A maximum of three mesocosms without replication was used within one experiment. Due to the large effort connected to a set-up of these dimensions, most published CEPEX studies (reviewed by Brockmann, 1990) report results from CEE mesocosms much smaller than these optimal dimensions. During POSER, Brockmann et al. (1983) compared phytoplankton and zooplankton succession in 1-2 m$^3$ and parallel bags of much larger dimensions. However, sinking flux lead to nutrient depletion in the surface layer within longer bags after a while, whereas growth in shorter bags was fuelled by remineralised nutrients (Kuiper, 1977). This principle applies mainly to simple bag constructions, where sinking material is not extracted during the experiment. A few m$^3$ was claimed to be sufficient to reproduce succession within size classes up to microplankton on short timescales. Introduction of carnivorous zooplankton like fish larvae poses additional requirements on the minimum volume of the experimental units (Kuiper, 1982). In this case the minimum size is given by the need to hold representative stock sizes of the larger animals as well
as their prey. Stock sizes have to be sufficiently large to enable representative sampling. In most experiments the number of trophic levels is reduced by removing large mesozooplankton or nekton.

Physical perturbations like temperature, light, turbulence or stratification, are for technical reasons mostly confined to land-based set-ups, whereas in situ pelagic mesocosms have been widely used to study chemical perturbations. The influence of anthropogenic impact on coastal communities due to increased nutrient runoff, atmospheric deposition, pollution by oil spills and especially heavy metals have been intensively studied in large mesocosm projects (Grice and Reeve, 1982). Most perturbation studies are targeted to detect thresholds of anthropogenic influence below which original biodiversity is widely preserved. Knowledge of these thresholds is necessary for policy makers to restrict emissions. Unfortunately, cost-intensive research such as mesocosm experiments become possible only once ecosystem services like fish yield and seaside recreational value or even the oceans' capacity as a dumping ground for toxic waste are endangered.

1.4 Thesis outline

This thesis documents the on-going technical development of a pelagic mesocosm system for quantitative measurement of biogeochemical fluxes. To date our investigations mainly focussed on testing the effect of projected future elevated aquatic CO₂ concentrations on carbon fluxes within plankton communities. The objective was to gain understanding of mechanisms and rates of conversion of dissolved inorganic carbon and nutrients into sinking particles or dissolved organics by a plankton community. The export of matter into deep waters is not only a function of photosynthetic production of particles, but depends much on the type of particles as well as their processing by the community. Especially within the context of man-made perturbation of global carbon cycles, the need of principle understanding of ocean carbon transport is urgently needed to ascertain projections of future global change. While hints from single ecosystem components tested are already abundant, integrated community experiments are rare. KOSMOS is a unique mobile platform for whole community experiments, applicable in most ocean regions. The KOSMOS mesocosms were often referred to as “giant test tubes”. Within this thesis an approach to observe reactants and products of a biological reaction within mesocosms is presented. A quantitative budgeting approach in mesocosms is a simple and obvious idea, often thought but hardly ever published. Following articles describe methods and first data on mesocosm carbon budgets within KOSMOS mesocosms.
Technical Note: A mobile sea-going mesocosm system – new opportunities for ocean change research

To meet the specific requirements for investigation of this global scale biogeochemical issue a specific mesocosm was designed. Other than eutrophication or pollution being relevant predominantly on a regional scale in coastal waters, ocean acidification is equally occurring in offshore waters far from human activity. The previously mentioned mesocosms (Fig. 1.1) are not suitable for unsheltered regions where swell or waves might occur. They were mostly operated on fixed locations within bays close to the operating research facilities. The mobile KOSMOS system is designed for moored or free drifting deployment from mid-size research vessels to achieve data covering a variety of locally different ecosystems. Constructional features making the set-up withstand waves up to two meters were continuously improved within the last five years and open relevant marine areas for research previously inaccessible to mesocosms. Strategies to reduce bio fouling on the mesocosm surfaces enable long term studies. In bringing together scientists from a wide variety of research disciplines achieved datasets comprehensively describing chemical and biological processes.

With the focus on biological carbon sequestration, net community production and the export of organic particles are central variables. To account for the direct quantitative observation of inorganic matter input and organic matter output of the plankton system, several analytical methods were developed, adapted or improved.

Technical Note: The determination of enclosed water volume in large flexible-wall mesocosms "KOSMOS"

Manuscript 2.2 describes a precise method for determination of the enclosed water volume, showing that equally manufactured and filled KOSMOS bags vary in volume by up to 8%. The volume of the reaction vessel has to be precisely known to allow quantitative comparison of measured fluxes to aquatic standing stocks of carbon and relevant nutrients like nitrogen, phosphorus and silica. Volume estimates relied on pumping rates during filling within published mass balance calculations. For KOSMOS mesocosms, filled by enclosing a water column, geometric calculations based on the intended shape and dimensions were used. Even in case the intended shape of the submerged bag is approximately achieved, there might be considerable variability in the enclosed water volume within a flexible bag.
Technical Note: A simple method for air–sea gas exchange measurements in mesocosms and its application in carbon budgeting

Publication 2.3 describes a newly developed method to directly determine gas exchange velocities and compares the results to relevant literature values. Whereas in earlier mesocosm studies dissolved inorganic carbon (DIC) was generally not measured, in some more recent experiments mesocosm integrated net community carbon uptake was calculated on the basis of changes in DIC and CO₂ gas exchange. It could be shown that laboratory or field derived parameterisations can not readily be used to calculate mesocosm gas exchange. Robust estimates of net community carbon uptake can be however derived using direct tracer measurements to estimate CO₂ air sea exchange.

Sediment sample processing

A description of sediment sample processing elaborated for the KOSMOS mesocosms is described in Section 2.4. In the KOSMOS set-up, the whole enclosure is funnel shaped on the bottom end, so that all sinking material is collected. The material can be easily sampled from the surface at any interval using a tube connecting the funnel tip with the water surface. Frequent sinking flux measurements allow for the detection of sedimentation events, analyses of sediment composition unspoiled by degradation and the calculation of elemental budgets for each sampling day.

Implications of elevated CO₂ on pelagic carbon fluxes in an Arctic mesocosm study – an elemental mass balance approach

Publication 2.5 presents data on carbon and nutrient budgets from a high Arctic Ocean acidification experiment. Applying the presented methods, a comprehensive dataset could be produced describing the effects of elevated aquatic CO₂ on elemental cycling within the enclosed ecosystem. Fertilising CO₂ effects on picoplankton significantly affected carbon and nutrient fluxes within the water column. Increased production of these small algae however, did not result in increased export of sinking particles but in accumulation of dissolved organics. Increased nutrient consumption as a consequence of CO₂ fertilised production resulted in significantly reduced export of diatom aggregates later in the experiment. The presented dataset underlines the important role of plankton succession and trophic interaction in modifying the consequences of physiological responses on the ecosystem level.
In Section 3, the improvements of the KOSMOS system after the 2010 Svalbard experiment are discussed. Most importantly instrumentation that allows preventing relevant wall growth by regular cleaning of the inside walls is presented. Furthermore, the bottom construction was improved for more efficient sediment and water column sampling. Gas exchange estimates have been improved using more sophisticated sampling protocols and online measurement of physical boundary conditions. Furthermore, mesocosm methods were developed to observe and retrieve large animals like juvenile fish, being present in very low numbers.

In the Perspective Section 4, the determination of general biogeochemical patterns and universal mechanisms from mesocosm research is discussed. Hypotheses and questions for future experiments focussing on biogeochemistry in tropical upwelling events are presented, together with a concept for technical realisation of upwelling experiments.

Abstract. One of the great challenges in ocean change research is to understand and forecast the effects of environmental changes on pelagic communities and the associated impacts on biogeochemical cycling. Mesocosms, experimental enclosures designed to approximate natural conditions, and in which environmental factors can be manipulated and closely monitored, provide a powerful tool to close the gap between small-scale laboratory experiments and observational and correlative approaches applied in field surveys. Existing pelagic mesocosm systems are stationary and/or restricted to well-protected waters. To allow mesocosm experimentation in a range of hydrographic conditions and in areas considered most sensitive to ocean change, we developed a mobile sea-going mesocosm facility, the Kiel Off-Shore Mesocosms for Future Ocean Simulations (KOSMOS). The KOSMOS platform, which can be transported and deployed by mid-sized research vessels, is designed for operation in moored and free-floating mode under low to moderate wave conditions (up to 2.5 m wave heights). It encloses a water column 2 m in diameter and 15 to 25 m deep (~50–75 m³ in volume) without disrupting the vertical structure or disturbing the enclosed plankton community. Several new developments in mesocosm design and operation were implemented to (i) minimize differences in starting conditions between mesocosms, (ii) allow for extended experimental duration, (iii) precisely determine the mesocosm volume, (iv) determine air–sea gas exchange, and (v) perform mass balance calculations. After multiple test runs in the Baltic Sea, which resulted in continuous improvement of the design and handling, the KOSMOS platform successfully completed its first full-scale experiment in the high Arctic off Svalbard (78°56.2'N, 11°53.6'E) in June/July 2010. The study, which was conducted in the framework of the European Project on Ocean Acidification (EPOCA), focused on the effects of ocean acidification on a natural plankton community and its impacts on biogeochemical cycling and air–sea exchange of climate-relevant gases. This manuscript describes the mesocosm hardware, its deployment and handling, CO₂ manipulation, sampling and cleaning, including some further modifications conducted based on the experiences gained during this study.

1 Introduction

Of the more than 260 scientific papers published until now on ocean acidification and its impacts on marine life less than 5% have been conducted on communities or ecosystems, with the vast majority of studies performed on individual species (Gattuso and Hansson, 2011). Extrapolating from organism-based effects to community and ecosystem impacts is difficult, because the observed responses are typically obtained in the absence of competition, trophic interactions, and with low or no genetic diversity (Riebesell and Tortell, 2011). For the same reasons parameterizations of biological processes in ecosystem and biogeochemical models based on physiological responses of individual organisms are problematic. In benthic systems, natural high CO₂ environments, such as CO₂-venting sites, provide a powerful test bed to assess effects of ocean acidification at the community and ecosystem level. Studies at volcanic CO₂ vents have revealed drastic changes in benthic community composition and biodiversity when compared to adjacent areas not exposed to high CO₂ (Barry et al., 2011). Because of
lateral advection and mixing of water masses, CO2-venting sites generally do not provide useful testing grounds to study ocean acidification impacts on pelagic communities (Riebesell, 2008). Oceanographic transects along natural CO2 gradients, e.g. from temperate to high-latitude waters (Charalampopoulou et al., 2011) or from recently upwelled high-CO2 waters downstream towards lower-CO2 waters (Beaufort et al., 2011), offer the opportunity for community-level comparisons. Because of the many other environmental factors varying in concert with CO2, the interpretation of observed biotic differences along those gradients is complex.

For pelagic systems mesocosms provide a powerful approach to maintain a natural community under close-to-natural self-sustaining conditions, taking into account relevant aspects from “the real world” such as indirect effects, biological compensation and recovery, and ecosystem resilience, which commonly are not accounted for in small-scale laboratory experiments (Riebesell et al., 2010). The mesocosm approach is therefore often considered the experimental ecosystem closest to the “real world”, without losing the advantage of reliable reference conditions and replication (Petersen et al., 2003). The main advantages unique to mesocosm experimentation are as follows:

1. The ability to investigate community dynamics of three or more levels for an extended period of time.
2. The ability to measure the pools and fluxes of bio-active and particle reactive elements and compounds and to perform mass balance calculations in complex systems.
3. The ability to study interactions of ecosystem dynamics and biogeochemical processes under experimental conditions.
4. The ability to bring together scientists from a variety of disciplines, ranging from, e.g., molecular and evolutionary biology, ecophysiology, marine ecology and biogeochemistry to marine and atmospheric chemistry.

It needs to be acknowledged, however, that some constraints of enclosures are to be considered when extrapolating mesocosm results to natural systems (see Riebesell et al., 2010, for a review). Enclosures of all kinds are inherently limited in their ability to include higher trophic levels (e.g. fish, seabirds and mammals), and to approximate vertical mixing of water column and small-scale shear occurring in nature (Menzel and Steele, 1978; Carpenter, 1996). Enclosure effects may also influence food web dynamics to varying degrees, creating trophic interactions that can differ with mesocosm dimension and which may deviate from those of the natural system intended to be mimicked (Kuiper et al., 1983; French and Watts, 1989, Petersen et al., 2009). Despite these difficulties and the intense debate they have spurred over the past decades (e.g. Pilson and Nixon, 1980; Brockmann, 1990; Drenner and Mazumber, 1999), mesocosm enclosure studies still remain the most generally applicable means to experimentally manipulate and repeatedly sample multi-trophic planktonic communities.

Considering the wide range of topics in ocean change research where mesocosm experimentation could greatly advance our science, there are surprisingly few marine mesocosm facilities in operation. Moreover, existing facilities are either stationary or confined to well-protected waters, limiting their scope of application. Here we describe a newly developed sea-going mesocosm facility which can be used in moored and free-floating mode under low to moderate wave conditions (up to 2.5 m wave heights). The new design in combination with new developments in mesocosm handling and sampling are intended to optimize mesocosm performance, prolong the duration of mesocosm experiments, and perform mass balance calculations by accounting for all relevant pools and fluxes of elements and compounds of interest.

2 Material and methods

Most of the following description relates to the 2010 experiment off Svalbard. The corresponding sections are written in past tense. Some aspects of the mesocosm hardware and handling used in 2010 were modified in subsequent experiments. To avoid providing detailed descriptions of the KOSMOS approach for each new experiment, we have included descriptions of those modifications in this manuscript. To distinguish between aspects specific for the 2010 experiment and those applicable to KOSMOS hardware and handling in general, we will use past tense in the case of the former and present tense for the latter.

2.1 Mesocosm hardware

The Kiel Off-Shore Mesocosms for Future Ocean Simulations (KOSMOS) consist of 9 mesocosm units, which are operated independently. Each unit comprises a floatation frame, the mesocosm bag, a bottom shutter and sediment trap, a dome-shaped hood on top of the floatation frame, weights at the bottom of the floatation frame and the lower end of the bags to maintain an upright position when exposed to wind and wave activity, and various ropes needed for mesocosm operation. The total weight of each KOSMOS unit, including all components described below, is approximately 1.7 tons.

2.2 Floatation frame

The KOSMOS floatation frame consists of six 7.5 m-long, 30 cm-diameter closed glass fibre tubes which are fixed to a steel structure in the lower part and by a steel metal ring at the top end. Steel weights are attached to the horizontal junctions at the bottom of the steel structure. The diameter of the glass fibre tubes, which generate the buoyancy, is reduced at and above the waterline to lower the up- and downward movement of the floatation frame due to wave action.
Fig. 1. Drawing of floatation frame with steel structure (lower part), glass fibre tubes for buoyancy, and steel ring at top, holding the dome-shaped PVC hoods. The tapering of the tubes in the above-surface section reduces buoyancy changes due to wave activity. Size indications in mm.

A dome-shaped roof made of polyvinyl chloride (PVC) covered with metal spikes is mounted on top of the floatation frame to reduce precipitation into the mesocosms and prevent seabirds from landing on the frame and defecating into the enclosures. The PVC foil has ca. 80% light transparency in the spectral range > 400 nm wavelength. Below 400 nm the transparency strongly decreases, largely precluding the penetration of UV light. A flashlight with light sensor, solar panels and radar reflector is mounted on top of the frame, intended to alert passing ships. A set of clamps on either side of the frame above the waterline serves to fix various ropes needed to unfold, fix and operate the mesocosm enclosures (see mesocosm filling below). At the time of deployment the mesocosm bag is folded in a pack positioned above the water line (as displayed in Fig. 1).

2.3 Mesocosm bags

The enclosure bags are made of thermoplastic polyurethane (TPU) with a thickness of 1 mm in the upper 7 m and 0.5 mm below that. The bag diameter is 2 m. The length of the bag can be selected according to the scientific question and the conditions at the deployment location. For the 2010 experiment a total length of 17 m, 2 m above and 15 m below the water line, with a volume of approximately 50 m$^3$, was chosen. Follow-up experiments in the Raunefjord south of Bergen, Norway, in June/July 2011 used bag total lengths of 25 m, and off Hawaii in November/December 2011 and in the Finnish archipelago off Tvarminne in June to August 2012 19 m bag lengths. To maintain an approximately cylindrical shape of the mesocosm bags, rings of 2 m inner diameter made of 4 cm polyethylene pipes are positioned every 2 m in ring-shaped pockets made of TPU foil fixed onto the outside of the enclosure bag by high-frequency welding (Fig. 2).

Measurements of light intensities taken in parallel inside the mesocosms and outside in the fjord yielded similar surface layer light intensities and similar depth profiles in the PAR spectrum (see also Schulz et al., 2013). Light transparency measurements of the TPU foil revealed nearly 100% absorbance of UV light. This together with the low light transparency below 400 nm of the PVC roof resulted in negligible UV light intensities inside the mesocosms.

2.4 Bottom shutter and sediment trap

At the bottom of the enclosure bag a steel ring holds two semi-circle plates made of 10 mm-thick Makrolon®. The plates are in upright position to allow water to enter the mesocosm bags during the lowering and unfolding of the bags (Fig. 3, left panel). A 2 m-long funnel-shaped sediment trap with a mouth of the same diameter as the mesocosm bag is connected to one of the bottom lids. It is tightly folded and attached between the bottom plates and unfolds and stretches automatically through an air-filled ring at the upper end of the funnel immediately after the bottom plates are closed (Fig. 3, right panel). A silicon tube connects to the lower end of the funnel from below the bottom lids and extends to the water surface on the outside of the mesocosms (Fig. 4). Material collected in the sediment trap is regularly sampled via this tube, using a manual vacuum pump system. Processing of the samples included sub-sampling for zooplankton counting, followed by concentrating the residual sediment material, freeze-drying, grinding and homogenizing for subsequent chemical analysis.

The sediment trap as described here created a "dead volume" underneath the funnel of approximately 8% of the enclosure volume. Because this water gradually exchanged with the rest of the enclosed water over one to two days, there was a dilution effect after experimental manipulations such as CO$_2$ enrichment and nutrient addition. This complicated determining precisely the start value of the applied
Fig. 2. Sketch of floatation frame with unfolded TPU enclosure bag; different colouring of the light-transparent bag indicates difference in TPU foil thickness: green, 1 mm; brown, 0.5 mm. The blue rippled plane represents the water line. At the bottom of the bag above the bottom plate the funnel-shaped sediment trap is indicated. The red line extending from the tip of the sediment trap to the water surface represents the tube used for sampling of sedimented matter.

Fig. 3. Sketches of bottom plate. Left: lids in upright position, as applied during filling of the enclosure bags. A removable net (grey shaded area) with a mesh size of 3 mm is mounted below the bottom ring. Each bottom plate is equipped with 8 screws for tightening the lids after closing. Right: bottom plate in closed position with unfolded sediment trap.

Fig. 4. Left: sketch of sediment trap used in 2011 and 2012 campaigns. The funnel-shaped trap made of TPU foil is connected to the bottom of the enclosure bag via a flange (right panel). Note the tapering of the lowest section of the mesocosm bag. Sampling of sedimented matter is achieved via a silicon tube which connects to a 5 l sampling flask and a hand-operated vacuum pump. Right: flange ring made of laminated fibreglass to attach the external sediment trap to the lower end of the enclosure bag. The upper ring (connected to the bag) is equipped with steel weights to facilitate the sinking of the enclosure bag during mesocosm filling and to keep the bag in vertical position when exposed to currents. Bag and sediment trap are fixed to the upper and lower flanges by stainless steel clamps pressing the TPU foil in notches. Upper and lower flanges are connected with eight screws and sealed with a silicon rubber fitting.

2.5 Mooring and deployment

The mesocosms can be operated in moored or free-floating mode. When moored, the mesocosms are deployed in groups of three at a distance of 30 to 50 m between mesocosm units (Fig. 5). Units of each group are connected to each other through ropes fixed to the floating frames at 2.5 m water depth. The groups are separated by approximately 50 m between each group and anchored on both ends with weights (1.2 tonnes) consisting of railway wheels. Buoys are mounted between mesocosms and the anchor weights to ensure that the downward pull generated by strong currents is absorbed by the buoys rather than acting directly on the mesocosms. When operated in moored mode, the water currents acting on the mesocosms should not exceed 0.5 knots to avoid strong vertical deflection of the mesocosm bags and wearing on the ropes. In free-floating mode, as applied in the 2011 campaign off Hawaii, a drogue was connected to one
end of the three mesocosms. The weighted drogue was hanging from a large buoy at 150 m water depth and thereby was exposed to water currents deviating from those at the surface. It served to generate a steady drag at one end of the mesocosm array in order to keep the mesocosms apart and in a straight line. In this mode there is no limit on the acceptable speed of water currents.

2.6 Filling and closing

The filling of the mesocosms started after all mesocosms were moored in position. For this the enclosure bags were untied at the bottom, allowing the weighted lower end of the bags to sink through the water column with open shutters until the bags were completely unfolded. With this approach the mesocosms were filled with minimal disturbance of the enclosed water body. To avoid capturing large organisms (e.g., fish, jellyfish) a removable net with a mesh size of 3 mm was mounted across the bottom opening. Several teams were involved in filling the mesocosms in parallel in close succession to reduce the effect of changing water masses due to lateral advection during the filling process. Nevertheless, because the mesocosms were not all filled simultaneously and because of possible small-scale patchiness in the plankton community (i.e., smaller than the distance between individual mesocosms), there was a risk of differences between enclosed water bodies in terms of seawater chemistry and plankton community abundance and composition. This could have caused large inter-mesocosm variability during the experiment. To minimize differences in starting conditions between enclosed water bodies, the mesocosms were left open for free exchange with the surrounding water for 48 h after filling. For this the bottom shutters were kept open and the upper part of the bags lowered to 1.5 m below the water surface with the top and bottom opening covered with a net of 3 mm mesh size. Test runs during previous years with dyes injected into the mesocosms indicated that, depending on bag length and current speed, a complete exchange of the enclosed water body occurs within 2–3 days. By gradually exchanging the enclosed and surrounding water masses, it is insured that spatial patchiness is averaged out over time. While the mesocosms were open for water exchange, frequent measurements were conducted for several chemical and biological parameters to test for differences between mesocosms. The absence of detectable differences in these parameters was a precondition for mesocosm closing.

The exchange between mesocosms and surrounding water was terminated by lifting the upper parts of the bags above the surface and having divers close the bottom plates. At this point the top and bottom nets are removed. With the closing of the bottom shutters the sediment trap, folded and fixed between the two bottom plates, unfolds and rises through an air-filled ring until fully extended (Figs. 2 and 3). The closing of the mesocosms marks the beginning of the experimental period.

As described above, bottom plate and internal sediment trap were replaced by a flange-connected external sediment trap after the 2010 campaign. In the following campaigns the sediment traps were put in place by divers after the full extension of the enclosure bags. In this new design the sediment trap also has the function of closing off the bottom of the bags. The sediment trap is put in place in two steps: initially it is connected by a hinge integrated in the flange (see Fig. 7, left side of the flange). At this stage the sediment trap is hanging parallel to the mesocosm bag, held by the hinge and tied to the first support ring. In a second step (e.g., on the following day), divers turn the lower flange ring in horizontal position to fully connect with the upper flange ring, thereby expending the TPU foil forming the funnel of the sediment trap. The two flange rings are tightly connected by 8 screws. As before, the mesocosms are closed by divers after 2–3 days of open exchange between mesocosm and surrounding water. After mounting of the sediment trap, three 5 kg weights are mounted at its lower end to keep the funnel stretched. A hose connected to the bottom of the funnel and reaching above the water surface is used for sampling of the sedimented material (Fig. 4).
2.7 CO₂ and nutrient manipulation

CO₂ enrichment was carried out by adding CO₂-enriched fjord water into the mesocosms. The addition of CO₂-enriched seawater increases dissolved inorganic carbon (DIC) while leaving total alkalinity constant, perfectly mimicking ongoing ocean acidification (cf. Schulz et al., 2009, Gattuso et al., 2010). With 9 mesocosms available for this study, the choice was made to apply a CO₂ gradient with 8 different CO₂ levels, duplicating only the ambient CO₂ conditions without CO₂ manipulation (considered as control). This approach involves the use of regression statistics for assessment of possible CO₂ effects. This choice was made for the following reasons:

(a) Because of the low number of experimental units available and considering the risk of losing one or several mesocosms (e.g. due to damage by ice floats), a CO₂-gradient approach carries a lower risk of failure compared to a replicated approach (e.g. 3 CO₂ treatments with triplicates each) relying on ANOVA statistics.

(b) If there is a threshold level for any of the CO₂/pH sensitive processes, a CO₂-gradient approach has a higher chance of detecting it.

(c) With a CO₂-gradient approach the opportunity arises to include one or two CO₂ levels outside the range recommended for ocean acidification perturbation experiments (Barry et al., 2010), which would be more difficult to justify if such extreme levels were replicated.

(d) Although CO₂ manipulation is relatively straightforward, it is challenging to precisely achieve the targeted CO₂ levels. While critical in a replicated approach, in a CO₂-gradient approach deviations from the targeted CO₂ levels can be tolerated.

It was decided to replicate the ambient CO₂ level (control treatment) in order to minimize the risk of completing the experiment with no control in case of losing one or several mesocosm units. The different CO₂ levels were randomly interspersed among the 9 mesocosms (cf. Riebesell et al., 2010). 

The CO₂-enriched seawater was prepared in a 1.4 m³ tank on land filled with filtered (pore size 20 µm) fjord water which was stirred by an electric propeller while aerated with pure CO₂ gas for approximately 24 h (Fig. 6). At this stage the CO₂ partial pressure in the water was close to saturation (pH ~ 4.4). 

The DIC concentration in the CO₂-enriched water was calculated based on measurements of total alkalinity, pH (presented in total scale unless stated otherwise), salinity and temperature, using the computer program CO₂SYS (Lewis and Wallace, 1997). Based on this the amount of CO₂-enriched water needed to achieve the target pCO₂ levels in the different CO₂ treatments was calculated. The CO₂-enriched water was filled into 25 L carboys and transported to the mesocosms. Depending on target pCO₂, between 0 and 320 L (see Schulz et al., 2013) of the CO₂-enriched seawater was injected into the mesocosms by means of a membrane pump and a dispensing device (termed "spider"; Fig. 7, right panel). To achieve an even distribution of the CO₂-enriched water throughout the mesocosms, the "spider" was
slowly moved up and down during the injection over the entire length of the enclosure bags (Fig. 7, left panel). Vertical pH profiles were conducted after CO₂ additions to check whether an even distribution was achieved.

The injection of CO₂-enriched water was done in steps over 4 consecutive days starting in the afternoon of 6 June (t−1). Two mesocosms served as controls, while 7 mesocosms were manipulated to establish treatments of elevated pCO₂ with an initial range of 185–1420 µatm. Mean values of pCO₂ during the experimental period ranged from 175–1085 µatm (for details see Bellerby et al., 2012). In mesocosms with no or low addition of CO₂-enriched water, similar amounts of filtered fjord water were added in order to apply the same physical perturbation to all mesocosms. Some fine-tuning to reach target CO₂ levels was conducted on 11 June (t4), at which time the target pCO₂ levels where reached with an offset generally smaller than ±50 µatm. After this no further CO₂ manipulation was done in any of the mesocosms. Because of the slow exchange of water in the “dead volume” below the sediment trap with that in the rest of the enclosure bag, there was a dilution of the initial CO₂ enrichment due to mixing of the CO₂ manipulated (open bag) and non-manipulated (“dead volume”) water during the first couple of days. Budget calculations based on carbonate chemistry measurements starting after CO₂ manipulations needed to account for this dilution effect (Czemy et al., 2012a, 2013; de Kluijver et al., 2013; Silyakowa et al., 2013).

In the early morning of 20 June (t13), inorganic nutrients were added using the same dispersion device as described above and shown in Fig. 7 at concentrations of 5 µmol L⁻¹ NO₃, 0.32 µmol L⁻¹ PO₄, and 2.5 µmol L⁻¹ Si. The precise amounts of inorganic nutrients added to each mesocosm were calculated based on volume determinations conducted for all mesocosms through salt additions on 3 June (t4) and 11 June (t6). For a detailed description of the volume determination see Czerny et al. (2012b).

Approximately 200 live adult pteropods (Limacina helicina) sampled individually from the fjord were added to each mesocosm during 11–13 June (t4–t6) to study their response to ocean acidification. For unknown reasons the pteropods rapidly disappeared from the water column. Some pteropods were collected in the sediment traps; others were seen by divers accumulating in the dead volume underneath the sediment traps. Very few specimen survived the experiment.

2.8 Cleaning of the mesocosm walls

To estimate the contribution of wall growth to the overall production and accumulation of particular organic matter (POM) in the mesocosms, the inside of the enclosure bags was cleaned with a ring-shaped brush on 7 July (t30). Various biological parameters were determined on suspended particulate matter immediately before and after brushing of the walls to quantify the amount of biomass released into the water column. As reported in Czerny et al. (2012a) on average 16% of the nitrate and 32% of the phosphate added on t13 had accumulated on the mesocosm walls due to biofilm formation on t30. In follow-up campaigns, the formation of biofilms on the inside of the enclosure bags (wall growth) was prevented by regular cleaning (once per week) with a ring-shaped, double-bladed wiper using a similar configuration as depicted in Fig. 8.

2.9 Sampling

Vertical profiles of temperature, conductivity, pH, oxygen, fluorescence, turbidity and light intensity were taken daily in each mesocosm and the surrounding water between 14:00 and 16:00 LT with a CTD60M (Sun and Sea Technologies). Sampling of seawater from the mesocosms was conducted with a depth-integrating water sampler (Hydro-Bios). The sampler is equipped with a pressure-controlled motor and continuously collects water (5 L volume) while being lowered from the surface to 12 m depth. Samples were collected in the morning between 9:00 and 11:00. In addition discrete samples were taken at fixed depths using Niskin bottles and pumping systems with sampling tubes lowered into the mesocosms (for details see M&M in the corresponding manuscripts). For measurements of DIC, total alkalinity, N₂O, inorganic nutrients, dissolved organic matter, volatile organic compounds, oxygen incubations, and other samples sensitive for contamination and gas exchange, subsamples...
Table 1. Starting conditions in the nine mesocosms (M1-M9) and the surrounding fjord water. Data for salinity, pH and oxygen concentration (determined in situ with a CTD equipped with pH and oxygen sensors) for day t-4, all others for day t0. pH is in total scale, concentrations for oxygen, nitrate, ammonium, phosphate and silicate are in µmol L$^{-1}$. See Schulz et al. (2013) for details on the methodologies.

3.1 Conditions in the fjord

At the time of mesocosm deployment Kongsfjorden off Ny-Ålesund was ice-free, while parts of the inner fjord were covered by sea ice. During the course of the study, the sea ice broke off and the glaciers surrounding Kongsfjorden started to calve. Floats of sea ice and glacier ice drifted towards the mouth of the fjord starting in mid-June. Most of the ice transport occurred along the northern side of the fjord, i.e. on the opposite side of the mesocosm mooring, following the general current pattern in the fjord system. At times of persistent north to north-east winds some ice floats occasionally drifted towards the mesocosm array. A 24 h ice watch was on duty for the duration of the experiment. In a few cases ice floats needed to be pushed out of their path by small boats to avoid collision with the mesocosms.

The initial pCO$_2$ of the ambient water in the fjord was $\sim 175$ µatm, corresponding to a pH of $\sim 8.3$ (Bellerby et al., 2012). Concentrations of mineral nutrients in the water were close to detection limit at the beginning of the experiment (0.11 µmol L$^{-1}$ of nitrate, 0.7 µmol L$^{-1}$ of ammonium, 0.13 µmol L$^{-1}$ of phosphate). Additionally, there were 5.5 µmol L$^{-1}$ of dissolved organic nitrogen, 0.20 µmol kg$^{-1}$ of dissolved organic phosphorus (Schulz et al., 2013) and 75 µmol L$^{-1}$ of dissolved organic carbon (Engel et al., 2013). Reduced pCO$_2$ and inorganic nutrient concentrations as well as increased concentrations of organic carbon, nitrogen and phosphorus indicated a post-bloom situation in the fjord at the start of the experiment.

3.2 Conditions in the mesocosms

Comparing the initial conditions after closing of the mesocosms provided an indication of the similarity between bags at the start of the experiment. As indicated in Table 1, the chemical conditions were almost identical in all mesocosms. Small differences between mesocosms and the surrounding fjord water were due to changing water masses in the fjord after closing the bags. Close agreement also exists for phytoplankton biomass and taxonomic composition (Table 2). Differences in group-specific chlorophyll a equiva-
lent concentrations between mesocosms for some of the taxonomic groups are more pronounced for those with predominantly large cell sizes combined with low abundances, such as diatoms and dinoflagellates. This difference is most likely due to a sampling bias rather than a true representation of biomass differences in the mesocosms. Almost identical concentrations in all mesocosms are obtained for bacteria and total virus counts (Table 2). Overall, the resemblance in initial values for a variety of chemical and biological parameters suggests proper conditions for the start of the experiment.

3.3 Temporal development

A short temporary increase in phytoplankton biomass during the first part of the experiment was probably fuelled by utilization of organic nutrients. Half way through the experiment inorganic nutrients were added to the mesocosms stimulating two additional phytoplankton blooms.

Based on the manipulations carried out over the course of the study, the deployment period is divided into 4 phases, one pre-experimental phase (phase 0) and three experimental phases (phases 1–3) as follows:

- phase 0: closing of the mesocosms until end of CO₂ manipulation (t-4 to t4),
- phase 1: end of CO₂ manipulation until nutrient addition (t5 to t12),
- phase 2: nutrient addition until 2nd chlorophyll minimum (t13 to t21),
- phase 3: 2nd chlorophyll minimum until end of experiment (t22 to t30).

The temporal changes in phytoplankton biomass and community composition observed in the mesocosms follow the same basic trends as those recorded in the waters surrounding the mesocosms (Brussaard et al., 2013; Schulz et al., 2013). Considering that lateral advection caused the water surrounding the mesocosms to exchange rapidly, the close agreement between enclosed and ambient plankton community development seems quite remarkable. This indicates that (1) major trends in plankton development persisted independent of small-scale patchiness in the study area and (2) the enclosed plankton community mimics the natural system reasonably well in terms of major developments in biomass and composition. The close agreement starts to weaken after nutrient addition in the mesocosms.

Aside from providing a comprehensive data set on plankton community responses to ocean acidification and their impacts on biogeochemical cycling, the study offered the opportunity for consistency checks between individual measurements. Particularly enlightening in this respect was the comparison of different approaches determining net community production, which was obtained from bottle incubations measuring O₂ production/consumption (Tanaka et al., 2013), estimates of changes in DIC concentration (Silyakova et al., 2013), and incorporation of ¹³C tracer added directly into the mesocosms (de Kluijver et al., 2013). These estimates were further compared with ¹⁴C incorporation determined in bottle incubations (Engel et al., 2013). While at first sight the different approaches appeared to yield different rates and – more surprisingly – different relationships...
Table 2. Concentrations of chlorophyll a equivalent (in ng L\(^{-1}\)) for eight taxonomic groups of phytoplankton determined from HPLC measurements using CHEMTAX and bacterial and viral numbers (10\(^6\) mL\(^{-1}\)) measured by flow cytometry for day 0. See Schulz et al. (2013) for details on methodologies. Abbreviations for taxonomic groups refer to prasinophyceae, dinophyceae, cryptophyceae, chlorophyceae, cyanophyceae, bacillariophyceae, chrysophyceae, and haptophyceae.

With CO\(_2\) concentration, closer examination yielded some interesting insights into the underlying processes and eventually resulted in a coherent interpretation of plankton community responses to ocean acidification (see discussions in references cited above).

4 Discussions

4.1 The study area

The Arctic Ocean ecosystem is expected to undergo major climate-change-related transformations in the coming decades, ranging from surface layer warming and freshening to enhanced stratification and loss of sea ice. Due to the high CO\(_2\) solubility and low carbonate saturation states of its cold surface waters, the Arctic Ocean is also considered particularly vulnerable to ocean acidification. If CO\(_2\) emissions continue to rise at current rates, half of the Arctic Ocean will be undersaturated with respect to calcium carbonate and, therefore, corrosive for calcareous organisms within the next three to four decades (Steinacher et al., 2009). While several Arctic calcifying species have been shown to respond negatively to ocean acidification (e.g. Bünzelnbender et al., 2011; Comeau et al., 2009; Lischka et al. 2011; Walther et al., 2010; Wood et al., 2011), little is known about possible consequences of ocean acidification at the base of the Arctic food web. The experiment described here was intended as a first attempt at closing this gap by conducting a pelagic mesocosm CO\(_2\)-enrichment study in Kongsfjorden on the western coast of Spitsbergen – about 1000 nautical miles south of the North Pole.

Kongsfjorden, an open fjord system without sill, is about 26 km long and between 4 and 10 km wide, with a maximum depth of 400 m. The water in Kongsfjorden is influenced by (i) Arctic water masses transported by the coastal current flowing from the Barents Sea over the West Spitsbergen Shelf, (ii) Atlantic water masses coming in with the northbound West Spitsbergen Current, and (iii) freshwater input from calving and melting glaciers as well as precipitation (Hop et al., 2006). Discharge of freshwater and sediments from the adjacent glaciers strongly varies seasonally, peaking in the summer. During winter, the inner part of the fjord is covered by sea ice, with large interannual variability in ice thickness, time of formation and break-up (see Svendsen et al., 2002, for a detailed review of the physical environment of the Kongsfjorden area).

In the fjord, the initiation of the phytoplankton spring bloom starts already under ice cover, culminating between April and early June after ice break-up (Eilertsen et al., 1989). The majority of studies conducted on the plankton community in Kongsfjorden focused on the spring period when high nutrient availability and increasing light levels support a substantial fraction of the annual primary production (Iversen and Seuthe, 2011; Seuthe et al., 2011). After the spring bloom, phytoplankton biomass remains moderately high during late spring and summer (Hop et al., 2002). At this time of the year, the plankton community is typically characterized by an efficient microbial loop (Iversen and Seuthe, 2011) that provides inorganic nutrients to phytoplankton and bacteria through rapid organic matter remineralization. These were the conditions encountered at the start of this mesocosm campaign. Accordingly, picoc- and nanophytoplankton groups were the dominant autotrophs during the first part of this study (Brussaard et al., 2013). Due to the low seed population of dinoflagellates and diatoms, the dominance of picoc- and nano-sized phytoplankton continued even after nutrient addition. The standing stock of microphytoplankton was building up slowly and dominated phytoplankton biomass only towards the end of the experiment (Schulz et al., 2013).
4.2 KOSMOS experimental facility

After a sequence of test runs in free-floating mode conducted in the Baltic Sea in 2006, 2007, and 2008, which led to considerable improvements in the mesocosm hardware and handling, and a four-week trial run in moored mode in 2009, which yielded some novel results on ocean acidification effects during a phytoplankton spring bloom (Schulz and Riebesell, 2012), the Svalbard 2010 campaign was the first full-scale experiment involving nine mesocosm units and covering a broad range of parameters over an extended period of time. Building on the experience gained during this campaign, this new sea-going experimental platform opens up new opportunities for mesocosm experimentation under a variety of hydrographic conditions and geographical locations. Important new features of this facility include

- the enclosure of large volumes (45–75 m³) with minimal disturbance of the enclosed water body and plankton community,
- controlled carbonate chemistry manipulation with minimal agitation of the enclosed water,
- mass balance calculations through precise determination of mesocosm volume by full accounting of all relevant pools and fluxes for key elements (carbon, nitrogen, phosphorus, silica),
- extended experimental duration through routine cleaning of mesocosm walls (preventing extensive wall growth) and regular sediment sampling (preventing release of remineralization products from sedimented matter),
- operation in moored and free-floating mode under low to moderate wave conditions allowing mesocosm experimentation in areas previously not amendable to this kind of experimentation.

This mesocosm campaign, which involved 35 scientists from 12 institutes, provided the opportunity for a highly integrative, multidisciplinary study involving marine engineers, molecular and marine biologists, ecologists, biogeochemists, and marine and atmospheric chemists. By covering a wide range of parameters measured over 35 days (4 days prior to and 31 days after the start of CO₂ manipulation), it provided a comprehensive data set on pelagic community-level responses to ocean acidification and their impacts on nutrient cycling and air–sea exchange of climate-relevant gases.

Acknowledgements. The design, construction and field testing of the KOSMOS mesocosms was made possible through financial support of GEOMAR and the integrated project SOPRAN (Surface Ocean Processes in the Anthropocene) funded by the German Ministry for Education and Research (BMBF). GEOMAR and SOPRAN provided the KOSMOS facility for the Svalbard 2010 experiment and organized the logistics leading up to and during the experiment. GEOMAR was responsible for deploying the mesocosms, running the experiment and coordinating all scientific aspects before, during and after the experiment. The scientific work is a contribution to the European Project on Ocean Acidification (EPOCA), which received funding from the European Community’s Seventh Framework Programme (FP7/2007–2013) under grant agreement no. 211384. Several participants of this study received funding from the European Community’s Seventh Framework Programme under grant agreement no 228224, MesoAqua. We gratefully acknowledge the logistical support of Greenpeace International for its assistance with the transport of the mesocosm facility from Kiel to Ny-Ålesund and back to Kiel. We also thank the captains and crews of M/V Esperanza of Greenpeace and R/V Viking Explorer of the University Centre in Svalbard (UNIS) for assistance during mesocosm transport and during deployment and recovery in Kongsfjorden. We thank the staff of the French-German Arctic Research Base (AWIPEV) at Ny-Ålesund, in particular Marcus Schumacher, for on-site logistical support.

Abstract. The volume of water enclosed inside flexible-wall mesocosm bags is hard to estimate using geometrical calculations and can be strongly variable among bags of the same dimensions. Here we present a method for precise water volume determination in mesocosms using salinity as a tracer. Knowledge of the precise volume of water enclosed allows establishment of exactly planned treatment concentrations and calculation of elemental budgets.

1 Introduction

Manipulation of a chemical parameter (e.g. nutrient or pollutant) in an experimental enclosure is usually accomplished by the following: (1) calculating the amount of the substance needed for a given volume of water, (2) adding the substance, (3) mixing the enclosed water to ensure homogeneity and (4) analysing the water to check if correct concentrations are achieved. In a large pelagic mesocosm like KOSMOS (Kiel Offshore Mesocosms for future Ocean Simulations) (~ 50–80 m³ within each unit), some of these steps are technically difficult. The precise volume of water cannot be easily measured using standard volumetric or gravimetric methods and, as shown in this article, geometric calculations do not deliver satisfying results for a flexible-wall enclosure. Distributing a substance within an up to 25-m-deep water column can lead to vertical concentration gradients, and active mixing requires a large energy input. When a sample is analysed, it might be already too late to detect applied treatment concentrations inside the mesocosm as they might be rapidly altered by biological activity. Uncertainties and variability in treatment levels and budget calculations can be largely avoided if the exact water volumes of individual mesocosms are known.

Many chemical parameters can be adjusted much more precisely as they can be determined later using seawater analytics. Here we present a method to precisely measure the volume within each experimental unit by addition of relatively small amounts of sodium chloride solution. Errors and uncertainties of the volume measurement are discussed.

2 Preparation of salt brine for volume measurements

Sodium chloride (NaCl) is used as a conductometric tracer for volume measurement because of its high solubility (359 g L⁻¹ at 20 °C). Complex sea salt mixtures cannot be prepared due to the relatively low solubility of some of the components. A NaCl concentration well below saturation (i.e. 250–300 g kg⁻¹) was chosen to ensure relatively quick dissolution and to prevent possible precipitation which could bias volume measurement. The source of the salt should be chosen with care, as impurities such as iron can cause enrichment of the enclosed water far beyond natural levels. To prevent this, one option is to use high purity grade salt. However, other salts are relatively pure and cost efficient depending on the production process. Attention should be paid to choosing a salt which does not contain commonly used anti-caking agents such as ferrocyanide (e.g. Brezelsalz Bäckerstoiz®, esco, Germany). The ion exchanger Lewatit™ MonoPlus TP 260® (Lanxess, Germany) removes metal anions efficiently from concentrated salt solutions. As soon as a sub-sample for calibration is taken after complete dissolution, the brine has to be stored in a tightly closed container to avoid evaporation. For a schematic drawing of our setup to prepare salt brine, see Fig. 1.

Published by Copernicus Publications on behalf of the European Geosciences Union.
Fig. 1. Schematic drawing of the setup used for the preparation of salt brine in large amounts. An electric outboard motor (a) in the mixing tank speeds up the dissolution of salts, enabling preparation of nearly saturated solutions within a few hours. Produced solutions can be further processed (e.g. run over filters or purifying columns) (b) and stored in intermediate bulk containers (c) and dispensed into suitable carboys for quantitative addition into the mesocosms using the “spider”.

3 Salt brine addition

Prior to brine addition the initial salinity in the mesocosms has to be determined precisely. Due to the slightly uneven shape of the enclosures, mean salinity of a CTD (conductivity, temperature and depth) profile made in a stratified mesocosm is not necessarily matching mean salinity of the same water without a salinity gradient (Fig. 2a). Therefore, the mesocosm water column has to be mixed prior to measurement until homogeneity is reached (if a salinity gradient is found). Mixing was performed by bubbling with compressed air for five minutes via a weighted (13 mm inner diameter) hose lowered to the bottom of the mesocosm. After determination of initial salinity by three consecutive CTD profiles, a precisely weighted amount of salt brine was injected into each mesocosm. Amounts of brine added were calculated based on an approximated volume to achieve salinity increases of 0.2 to 0.4. The “spider” system (described by Riebesell et al., 2012) was designed to evenly distribute liquids of any density inside large mesocosms. The brine solution was pumped through the “spider” system which was continuously moved up and down the upper ~90% of the mesocosm depth, avoiding any resting of the device at the lowest point. Once the brine solution has been pumped into the mesocosms, the empty solution container was rinsed twice with mesocosm water and the remaining water was pressed out of the “spider” using compressed air. The established salt gradient with decreasing water density with depth is not stable. An overturning circulation mixes the water column during the following 12 h as light, low-salinity water is making its way up across the denser, high-salinity water sinking to the bottom (Fig. 2b). While temperature gradients establish within hours according to outside stratification, salinity distribution remains homogeneous throughout the procedure. A stable halocline can be later established by purposeful salt brine addition to deep water layers or by freshwater input to the surface.

4 Salinity measurement

Salinity profiles were collected using a data-logger-equipped, hand-held, multisensory CTD CTD60M (Sun and Sea Technologies), manually lowered at a speed of ~0.2 m s⁻¹. Reproducibility of mean salinity (standard deviation of mean salinity from three replicate profiles (n ~ 300 single measurements per profile) in four salinity measurements) was typically ≤ 0.0003 units. This is corresponding to a measurement-derived uncertainty for volume estimates of ~ 0.1% for a salt addition increasing salinity (S) by 0.3.

5 Calibration

The calibration of the salt brine was performed at 20 °C in the laboratory, using surface water collected in the Flensburg Fjord (S = 17.0). Nine different mixing ratios were measured to construct a calibration curve (Fig. 3). For this, seawater has to be stirred in an appropriate calibration beaker to establish a constant flow across the salinity sensor of the CTD probe for a stable reading. Determination of initial salinity in the calibration beaker was followed by a first addition of brine, oriented at the largest expected mesocosm volume (highest dilution). Afterwards salinity was increased in small steps until the mixing ratio of the smallest expected mesocosm volume was reached. After plotting the first calibration curve, the batch of water was mixed again and a second calibration starting at S = 17.1 was performed. Although conductivity was increased by NaCl addition and not using a complex sea salt mixture, measured increases in salinity were directly proportional to the added amount of salt brine. The algorithm used by our CTD (UNESCO PSS-78) assumes seawater ion composition to be conservative.
Salinity

Fig. 2. (a) A natural vertical salinity profile in a 25-m-deep mesocosm (blue dots). The average salinity of the profile is indicated by a vertical blue line. Red dots are salinity measurements after mixing the water column using 5-min bubbling with compressed air. Differences are caused by the uneven shape of the bag (here especially the bottom funnel) (b) The black profile is collected right after injecting salt brine to the upper 22 m of the mesocosm, the blue profile is measured 6 h later and the red profile 18 h later. (c) Homogeneous S profile shown in (a) is increased in three steps, measured on three consecutive days using three replicated profiles shown as black, red and gray dots.

When calculating salinity from conductivity and temperature. However, changes in sea salt composition were found to have no significant influence on volume determination using this protocol.

When the gravimetric mixing ratio of seawater in the beaker per added brine (SW: Brine (kg)) is plotted versus measured salinity increase (ΔS), a power fit can be used to calculate volumes of mesocosms from ΔS (X) by multiplication of the mixing ratio (Y) with the added mass of brine (Fig. 3). To determine the precision of volume measurements, three consecutive salt additions were performed in a 25-m-deep mesocosm on a test cruise in the Flensburg Fjord in the western Baltic Sea in January 2011 (Fig. 2c).

Fig. 3. Salt calibration curve. Exponential fits for two calibration datasets: calibration 1 (blue curve) is measured by increasing salinity from natural Baltic seawater S = 17; calibration 2 (black curve) is done after salinity was already increased from 17 to 17.1 by NaCl addition. Power formulas can be used to calculate mesocosm volume by multiplying y with the added amount of brine.

6 Potential side-effects of volume measurements using NaCl as a tracer

Every perturbation of the enclosed ecosystem in a mesocosm bares the risk of biasing results and reducing comparability to the natural system. Experiments on enclosed ecosystems cannot, however, be done without significant changes to natural physical and chemical side parameters such as turbulence, light or artificial nutrient additions. Perturbations equally performed in all parallel mesocosms are unproblematic when effects are compared among treatments. Homogenisation of the initial stratification and the addition of salt are equally performed in all units. Bubbles used to mix the mesocosms in the beginning of the experiment are presumably stressful for some of the enclosed organisms and might change initial dissolved gas concentration. Initial mixing of the water column in the beginning of the experiment has, beside the measurement of the salt inventory, a further advantage: it equalises differences in vertical nutrient distribution among parallel treatments arising from partial disruption of stratification after closing of the mesocosms. Harmful effects of temporary short bubbling on gases or organisms were not observed in prior experiments. In order to minimise stress on the enclosed ecosystem, the mesocosms should be mixed with large bubbles and not longer than absolutely necessary. Reports on physiological responses to a salinity increase of less than 1 could not be found for marine organisms. A minimum in species richness at intermediate salinities is observed along the natural salinity gradient (0 to 34) of the Baltic Sea estuary. However, changes in species distribution are generally attributed to salinity changes of
Table 1. Volumes calculated for three salinity additions to the same mesocosm using two calibrations, Cal 1 and Cal 2, were applied to each individual salinity increase. Results were corrected for increasing volume due to the addition of brine.

7 Discussion of measurement errors

Volumes calculated from three consecutive salt additions to the test mesocosm are summarised in Table 1. Deviations of about $\pm 1\%$ are larger than expected from possible uncertainties in the amount of brine added and the precision of salinity measurements. Based on the reproducibility of measurements we would expect uncertainties of only up to $\pm 0.1\%$. With respect to the good reproducibility of salinity measurements inside the mesocosms, enrichments of 0.3 to 0.4 during the Baltic Sea test turned out to be unnecessarily high. Comparable results could have been achieved applying salinity increases of less than 0.1. Actual losses during addition of brine can be expected to be on the order of single gram. Observed deviations are therefore unlikely to be caused by addition or measurement errors inside the mesocosms, but from uncertainties arising from the calibration. Calculated volumes based on three salinity additions to the same mesocosm and two calibration curves were used to identify uncertainties. Using either calibration 1 or 2, results of the consecutive measurements vary by the same percentage ($\sim 0.9\%$); however, using calibration 1, mean volume is 1.2\% higher than volume calculated using calibration 2. This offset is obviously due to a $\sim 0.003$ uncertainty in calibration initial $S$, to which all $\Delta S$ values in the calibration curve are referenced. Parts of the calibration limitation might have been due to problems in measuring salinity with a CTD probe inside a beaker. Consequently, the method is more sensitive in determining differences between mesocosms than in determining the absolute amount of water enclosed. Most accurate results can be expected when calibration is done using seawater at in situ $T$ and $S$, and the initial salinity is repeatedly measured.

8 Observed variability between mesocosms

Despite their nearly cylindrical appearance, measured volumes of nine KOSMOS mesocosms in two experiments deviated by up to 8\% between parallel units (standard deviation of $\sim \pm 3\%$; Table 2). The 25-m-deep setup in the Bergen 2011 experiment had slightly larger deviations than the 15-m-deep setup used in Svalbard 2010. The volumes of the 25-m-long bags were 4\% smaller than their geometrically calculated volumes during the test in the Baltic Sea. In Bergen 2011 the volumes of the same bags were averaged 3.3\% larger than geometrically calculated. These differences were probably caused by differences during filling – especially opening time – changing water densities, and slight lateral deformations caused by water currents acting on the moored mesocosms. During an earlier test cruise more than 20\% variation was measured between three mesocosms filled at a relatively strong current.

Abstract. Mesocosms as large experimental units provide the opportunity to perform elemental mass balance calculations, e.g. to derive net biological turnover rates. However, the system is in most cases not closed at the water surface and gases exchange with the atmosphere. Previous attempts to budget carbon pools in mesocosms relied on educated guesses concerning the exchange of CO2 with the atmosphere. Here, we present a simple method for precise determination of air–sea gas exchange in mesocosms using N2O as a deliberate tracer. Beside the application for carbon budgeting, transfer velocities can be used to calculate exchange rates of any gas of known concentration, e.g. to calculate aquatic production rates of climate relevant trace gases. Using an arctic KOSMOS (Kiel Off Shore Mesocosms for future Ocean Simulation) experiment as an exemplary dataset, it is shown that the presented method improves accuracy of carbon budget estimates substantially. Methodology of manipulation, measurement, data processing and conversion to CO2 fluxes are explained. A theoretical discussion of prerequisites for precise gas exchange measurements provides a guideline for the applicability of the method under various experimental conditions.

1 Introduction

Pelagic mesocosms represent large volume (mostly between one and fifty m³) experimental enclosures used to gather data on natural plankton communities (Petersen et al., 2003). Generally open towards the atmosphere, mesocosms, however allowing for air–sea gas exchange, make it difficult to calculate production or consumption of CO2 and other volatile compounds inside an experimental unit. Climate relevant trace gases and other volatile carbon compounds produced in marine environments are increasingly investigated for their potential climate feedbacks and have been measured in previous mesocosm experiments (Sinha et al., 2007; Archer et al., 2012; Hopkins et al., 2012). Observed concentrations in a mesocosm are a product of water-column reactions and losses or gains from the atmosphere. Precise knowledge of air–sea gas exchange rates can be used to calculate net production rates of these compounds in the water column, which can be compared between various experiments. Aquatic production rates in concert with data on biological community composition and physiological state would help to understand observed open-ocean distributions.

Not only in the context of global change, biological CO2 fixation and consequent carbon export by sinking particles is of special interest to biogeochemical experimentalists. Most mesocosm studies currently focus on investigating ecological interactions applying standard oceanographic methods on subsamples of the enclosed water. In principal, mesocosm experiments also provide the opportunity to compare biogeochemical element fluxes such as air–sea gas exchange and export to water-column production. With production rates, as usually measured in side experiments (e.g. O2 production or 14C incorporation), uncertainties arise from sample transfer into bottle incubations and from extrapolating back from incubation conditions to temperature and light gradients present in mesocosms. In situ primary production measurements using the whole enclosure as experimental vessel have to be elaborated, in order to produce estimates comparable to total mesocosm fluxes like sedimentation of organic matter. Calculating carbon fluxes from water-column pools of inorganic and organic carbon quantitatively related to air–sea fluxes and export rates could largely improve the
understanding of the system (Czerny et al., 2012a). To directly estimate cumulative net community production (NCP), changes in total dissolved inorganic carbon (CT) have to be corrected for CO₂ air-sea gas exchange and eventually for calcification and evaporation. In previous mesocosm experiments in a Norwegian fjord (Deилille et al., 2005) and indoors (Wöhlers et al., 2009; Taucher et al., 2012), net community production (NCP), calculated on the basis of measured changes in CT, were presented. To calculate air-sea gas exchange, Deилille et al. (2005) used a parameterisation for wind dependent boundary layer thickness achieved from experimental data compiled by Smith (1985). Wind speed, the crucial input parameter, was set to zero, because the mesocosms were closed to the atmosphere and moored in a sheltered surrounding. Whereas most parameterisations result in zero gas exchange at zero wind speed (Wanninkhof, 1992), laboratory derived wind dependent parameterisations by Smith et al. (1985) resulted in positive exchange at zero wind speed. Under calm conditions, gas exchange is low, but not zero; it is governed by other energy inputs than wind, e.g. thermal convection due to evaporation and temperature changes (Liss, 1973; Wanninkhof et al., 2009). Although direct wind forcing might be negligible in most mesocosms, the general assumption that overall energy input is comparable to the conditions in the experimental tanks used by Smith et al. (1985), however, is not justifiable. Surface turbulence in many mesocosm experiments is unlikely to be very low. Active mixing systems, wave movement of the surrounding water, thermal mixing or the deployment of sampling gear might create turbulence within the enclosures, comparable to quite windy conditions. Taucher et al. (2012), for example, found wind speeds of more than 6 m s⁻¹ to be necessary for balancing the carbon budget in a Kiel indoor mesocosm experiment, applying the Smith et al. (1985) calculation. Parameterisations for wind speed dependent gas exchange over the ocean are obviously not suitable for calculating mesocosm air-sea gas exchange. Other than open-ocean gas exchange measurements, direct measurement of exchange velocities in an enclosed water volume can be relatively easily done. Here, we present a simple method for direct measurements of air-sea gas exchange rates in mesocosms experiments using N₂O as a tracer. N₂O is a perfect choice as a gas tracer in this application, due to its well known atmospheric concentration, relatively simple detection and structural similarity to CO₂. Although N₂O is not an inert gas, conditions favouring its biological production are unlikely to occur in pelagic mesocosms. Possible bias by biological activity is assessed by parallel measurement of natural variations in N₂O and will be discussed later in the manuscript. The conversion of measured N₂O exchange rates to those of CO₂ and other gases is explained. We are providing a detailed description of the method and calculations including a discussion of prerequisites to achieve high quality data.

The measurement protocol and results are explained using a KOSMOS (Kiel Off Shore Mesocosm for Ocean Simulation, Fig. 1) experiment on ocean acidification in the Arctic as a model. Applicability of the method in the Kiel indoor mesocosm facility is further explained and discussed.

2 Methods

2.1 Setup of the Svalbard 2010 ocean acidification experiment

Nine 15 m deep KOSMOS mesocosms, each with a diameter of 2 m were moored end of May 2010 in the Kongsfjorden, Svalbard. Seven different CO₂ treatment concentrations were achieved through addition of CO₂ saturated seawater. While the ambient (~180 µ atm pCO₂) control treatment was replicated twice, the seven enriched mesocosms followed a gradient up to ~1420 µ atm pCO₂. Development of the enclosed natural plankton community was followed for 30 days after CO₂ manipulation, including addition of inorganic nutrients on day 13. For more details see Riebesell et al. (2012) and Schulz et al. (2013).

2.2 N₂O addition

One litre of saturated N₂O solution (N₂O medical, Air Liquide, purity > 98%) was prepared via bubbling of seawater for two days in a narrow measurement cylinder covered with Parafilm®. Amounts of the solution to be added to the mesocosms were calculated using solubility constants by Weiss and Price (1980) with respect to in situ salinities (S) and temperatures (T). The targeted concentrations of N₂O should be adapted to the setup in order to achieve mesocosm to air fluxes, which can be measured at good precision over reasonable time scales. Here, seawater tracer concentrations were chosen in accordance to the highest certified reference material for N₂O analyses available in our lab (~55 nmol kg⁻¹).

Assuming a background concentration of 13 nmol kg⁻¹, 40 nmol kg⁻¹ of medical grade N₂O was added. Based on experience, a surplus of approximately 20% was added to the mesocosms to account for losses unavoidable during handling of the solution.

Addition of the solution to the mesocosms (about 1-2 mL m⁻²) can be calculated according to the formulation:

\[
V_{ad} = \frac{V_w \cdot ad}{K_{TS} \cdot p}, \tag{1}
\]

where \(V_{ad}\) is the volume of N₂O stock solution added (L), \(V_w\) the volume of the mesocosm (L), ad the desired addition (mol L⁻¹), and \(K_{TS}\) is the solubility constant by Weiss and Price (1980) for S and T of the N₂O stock solution (mol L⁻¹ atm⁻¹) prepared at a pressure, \(p\) (atm), of one atmosphere.

A syringe with a large inlet diameter was used to transfer the stock solution carefully. Filling of the syringe was done...
slowly as vacuum increases undesired outgassing of N$_2$O. The stock solution was first diluted with filtered seawater in 25 L carboys, which were filled almost to the rim. The content of the carboys was homogeneously distributed to the mesocosms by using the pumped injection device “Spider” (Riebesell et al., 2012).

2.3 Sampling

Three of the nine mesocosms were sampled every second day using integrating water samplers (IWS, Hydrobios). Equal amounts of sample were sucked into the sampling bottle at each depth between 0 and 12 m, electronically controlled via hydrostatic pressure sensors. These integrated water samples represent inventories of the 15 m deep water column. Triplicate samples were drawn directly from the sampler. The water was filled bubble free into 50 mL headspace vials via a hose reaching to the bottom of the vial. The vial volume was allowed to overflow about four times before closing. Vials were closed with butyl rubber plugs (N 20, Machery and Nagel), crimp sealed and stored at room temperature after addition of 50 µL of saturated mercury chloride solution.

2.4 Measurement procedures

Measurement of aquatic N$_2$O concentrations was performed via gas chromatography (GC) with electron capture detection (Hewlett Packard 5890 II), using a headspace static equilibration procedure as described by Walter et al. (2006, precision $\sim \pm 1.8\%$). The GC was equipped with a 6'1/8" stainless steel column packed with a 5 Å molecular sieve (W. R. Grace & CO) and operated at a constant oven temperature of 190 °C. A 95/5 argon-methane mixture (5.0, Air Liquide) was used as carrier gas. 10 mL of helium (5.0, Air Liquide) headspace was added to the sample vials and later injected into the sample loop of the GC after equilibration was achieved by manual shaking and storage of the vials for at least 10 h at a temperature of 21 °C. Certified gas mixtures of N$_2$O in artificial air (Deuste Steininger GmbH) with mixing ratios of 87.2 ± 0.2, 318 ± 0.2 and 1002 ± 0.2 ppb as well as 1:1 dilutions with helium were used to construct calibration curves with a minimum of three data points close to sample concentrations. Headspace to water phase ratios in the vials was determined gravimetrically.

Total dissolved inorganic carbon (CT) was determined via coulometric titration using a SOMMA system and total alkalinity (TAlk) via potentiometric titration (Dickson, 1981) (standard error of both methods $\sim \pm 1 \mu$mol kg$^{-1}$). CO$_2$ concentrations, partial pressures and pH (total scale) were calculated from CT and TAlk measurements with the program CO2SYS by Lewis and Wallace (1995). For more details on carbonate chemistry see Bellerby et al. (2012).

Determination of salinity and temperature in the mesocosms was performed with a data logger-equipped hand held multisensory CTD 60M (Sea and Sun Technology).
3 Results and discussion

Concentrations of N$_2$O added on day 4 decreased in the enriched mesocosms from initially measured ~50 nmol kg$^{-1}$ on day 6 to ~30 nmol kg$^{-1}$ on day 28 (Fig. 2). Concentrations measured in the fjord close to the mesocosms were slightly oversaturated compared to atmospheric equilibrium values, calculated for in situ seawater $T, S$ and atmospheric mixing ratios measured close by on Zeppelin Mountain. Despite variable wind conditions, the concentration decrease inside the mesocosms could be fitted ($R^2 = 0.96$) using a standard diffusion relationship:

$$C_{N_2O} = 60.556 \cdot e^{-0.0241 \cdot d}$$

where the concentration of N$_2$O ($C_{N_2O}$) is described as an exponential function of the sampling day ($d$).

3.1 Calculation of CO$_2$ fluxes from changes in N$_2$O concentrations

Daily N$_2$O fluxes were calculated from the fitted N$_2$O concentration decrease over time and converted to volumetric units. Changes in the N$_2$O inventory, derived using the determined volume of the mesocosms (method described in Czerny et al., 2012b) were used to calculate fluxes in µmol cm$^{-2}$ h$^{-1}$ ($F_{N_2O}$) across the water surface according to

$$F_{N_2O} = \frac{I_{w1} - I_{w2}}{A \cdot \Delta t}$$

where $I_{w1}$ is the fitted bulk water N$_2$O inventory in µmol per mesocosm on $t_1$ and $I_{w2}$ on $t_2$ with $\Delta t$ the time interval between $t_1$ and $t_2$ in h, while $A$ is the nominal surface area of the mesocosm in cm$^2$. A N$_2$O transfer velocity ($k_{N_2O}$) in cm h$^{-1}$ is then calculated by dividing $F_{N_2O}$ by the concentration gradient according to Eq. (4):

$$k_{N_2O} = \frac{F_{N_2O}}{(C_{N_2O, w} - C_{N_2O, aw})}$$

where $C_{N_2O, w}$ is the fitted bulk water N$_2$O concentration (µmol cm$^{-3}$) at the point in time and $C_{N_2O, aw}$ the calculated (Weiss and Price, 1980) equilibrium concentration of N$_2$O with the atmosphere at prevailing bulk water $T$ and $S$. Using bulk water concentrations to derive a surface diffusion gradient perfect mixing of the mesocosm appears to be an absolute requirement. Referring from N$_2$O to inert gases with air–sea gas exchange being the only exchange process, it is irrelevant whether exchange is limited by mixing processes close to the air–sea interface or within the water column. Yet, if a permanent stratification is formed inside the mesocosm, the decrease of N$_2$O bulk water concentration cannot be used to calculate mesocosm–atmosphere CO$_2$ exchange. Processes modulating the concentrations of biologically active compounds such as CO$_2$ are usually variable along the light gradient. Therefore, due to shallow primary production, considerable differences in the surface gradient of CO$_2$ might emerge compared to N$_2$O surface gradients that are governed by diapycnal mixing. For stratified mesocosms, gas exchange calculations require the integration of information about vertical distribution of tracer and gases of interest. Here, N$_2$O and CO$_2$ inventories have to be determined by integrated water samples independently from surface gradients determined from discrete surface water samples. Regardless of the specific sampling strategy applied, it is imperative to use the same protocol for the tracer as for the gases of interest.

Due to convection caused by slight temperature changes in the surrounding water (Fig. 5) and an evaporation induced salinity increase (Schulz et al., 2013), the mesocosms in the Svalbard KOSMOS study could be considered to be homogeneous on time scales relevant for air–sea gas exchange. N$_2$O as well as CO$_2$ surface concentrations are therefore adequately represented by bulk water measurements.

$k_{N_2O}$ can be translated into a transfer velocity for any other gas using its Schmidt numbers to correct for gas specific
properties as shown for the transfer coefficient of CO₂ ($k_{CO₂}$) in Eq. (5):

$$k_{CO₂} = \frac{k_{N₂O}}{\frac{S_{CO₂}}{S_{N₂O}}}^{0.5}. \quad (5)$$

The Schmidt number for N₂O ($S_{N₂O}$) published by Rhee (2000), and the Schmidt number for CO₂ ($S_{CO₂}$) derived from diffusion coefficients published by Jähne et al. (1987) were used. Using this pair of Schmidt numbers, $k_{CO₂}$ is generally less than 1% smaller than $k_{N₂O}$, similarly to when both Schmidt numbers are derived from coefficients published by Jähne et al. (1987). If both coefficients are taken from Wilke and Chang (1955) the difference is ~10% and can become larger than 25% if $S_{CO₂}$ from Wilke and Chang (1955) is paired with ($S_{N₂O}$) derived from coefficients published by Broecker and Peng (1974). More recent wind and wave tank experiments have shown that a conversion of $k_{N₂O}$ to $k_{CO₂}$ is not necessary as gas exchange of the two gases is indistinguishable under conditions were chemical enhancement of CO₂ exchange is not relevant (Degreif, 2006). Fluxes for CO₂ ($F_{CO₂}$) can then be calculated by multiplication of $k_{CO₂}$ with the diffusion gradient between bulk water CO₂ concentrations ($C_{CO₂,w}$) and calculated equilibrium concentrations with the atmosphere ($C_{CO₂,a}$) as

$$F_{CO₂} = k_{CO₂} \cdot (C_{CO₂,w} - C_{CO₂,a}). \quad (6)$$

Daily CO₂ fluxes were calculated for the nine mesocosms within the Svalbard ocean acidification experiment (Fig. 3). In the first days after CO₂ addition was completed (day 4), maximum efflux of ~2 μmol CO₂ per kg seawater was observed in the highest CO₂ treatment (~1400 μatm) at a CO₂ gradient of ~980 μatm. In the following two weeks, the CO₂ gradient was diminished by outgassing CO₂ in concert with biological uptake, so that fluxes on day 27 were considerably lower (gradient ~450 μatm). Decrease of fluxes as a result of decreasing CO₂ gradients was less pronounced in the more moderately oversaturated mesocosms due to a higher buffer capacity of the carbonate system. About 0.5 μmol kg⁻¹ d⁻¹ CO₂ gassed into the water from the atmosphere in the non-manipulated control treatments (~175 μatm). Here, biological uptake was roughly balanced by influx so that the gradient remained rather constant over time.

3.2 Chemical enhancement of CO₂ air-sea gas exchange

Another correction has to be applied to derive accurate CO₂ fluxes in calm environments like the KOSMOS mesocosms. As CO₂ reacts with water, unlike N₂O, CO₂ gas exchange might be chemically enhanced due to buffering of diffusive concentration change by equilibration reactions within the boundary layer. Other than inert gases, CO₂ diffuses are not necessarily exchanged through the boundary layer, but can also be formed from bicarbonate close to the interface. This applies only at low wind speeds and not when mixing is considerably faster because CO₂ hydration kinetics are slow. Thus, chemical enhancement is thought to be rather insignificant under turbulent conditions relevant for open-ocean CO₂ exchange (e.g. when $k > 5$ cm⁻¹), but applies to the conditions found inside the mesocosms ($k \approx 1.8-2.5$ cm⁻¹) (Wanninkhof and Knox, 1996). Moreover, the state of the carbonate system determines the extent of chemical enhancement, being negligible at pH < 6 and substantial at pH > 8. In the Svalbard ocean acidification experiment, the treatment pH (total scale) ranged from 7.5 to 8.3 (Bellerby et al., 2012), therefore chemical enhancement created a pH effect on carbon flows that must be considered. To correct for this, theoretical parameterisations by Hoover and Berkshire (1969) were chosen, as currently no empirical parameterisations exist sufficiently describing the process in natural seawater (Wanninkhof and Knox, 1996). The enhancement factor α, the ratio between chemical enhanced flux and not enhanced flux can be calculated using Eq. (7):

$$α = \frac{τ}{[(τ - 1) + \tanh (Qz)/(Qz)]}. \quad (7)$$

Here, dimensionless $τ = 1 + [H⁺]²(K₁⁺K₂⁺ + K₁⁺[H⁺])^{-1}$, with $K₁⁺$ and $K₂⁺$ being the first and second stoichiometric equilibrium constants for carbonic acid and $[H⁺]$ the proton concentration. $Q = (τD^{-1})^{0.5}$ in cm⁻¹, where $D$ is the diffusion coefficient for CO₂ by Jähne et al. (1987) and $r$ describes the hydration of CO₂ either directly or via true carbonic acid. $r$ in the unit s⁻¹ can be calculated using Eq. (8):

$$r = K_{CO₂} + K_{OH⁻}K_{w}[H⁺]^{-1} \quad (8)$$

with $K_{CO₂}$ being the CO₂ hydration rate constant (s⁻¹), $K_{OH⁻}$ the CO₂ hydroxylation rate constant (L mol⁻¹ s⁻¹)
from Johnson (1982) and $K^*$ is the equilibrium constant for water. The boundary layer thickness $z$ (cm) can be calculated from determined transfer velocity ($z = D_k \text{CO}_2$). All constants used here can be found in Zeebe and Wolf-Gladrow (2001). Using the Hoover and Berkshire (1969) model, input conditions similar to our experimental conditions in Svalbard ($T = 5^\circ C$, $S = 35$, $z = 0.002$ cm, $\text{pH}_{\text{tot}} = 8.2$) result in enhancement of about $8\%$ ($\alpha = 1.082$). For the same conditions, but at a temperature of $25^\circ C$, $\text{CO}_2$ gas exchange would be enhanced by about $48\%$ ($\alpha = 1.479$).

Chemical enhancement factors using more complex models published by Quinn and Otto (1971), Emerson (1975), Smith (1985), and Keller (1994) give very similar results to the Hoover and Berkshire (1969) model (Wanninkhof and Knox, 1996). Experimental data from tank experiments reproduce calculated chemical enhancement relatively well (i.e. Hoover and Berkshire, 1969; Liss, 1973; Wanninkhof and Knox, 1996; Degreif, 2006). The simple pH dependent fit derived from enhancement experiments in natural Baltic seawater published by Kuss and Schneider (2004) is not recommended for use, as influences of $T$, $S$ and $z$ are not considered.

The relevance of chemical enhancement for open-ocean $\text{CO}_2$ exchange is controversial as the calculation of chemical enhancement factors using more complex models published by Quinn and Otto (1971), Emerson (1975), Smith (1985), and Keller (1994) give very similar results to the Hoover and Berkshire (1969) model (Wanninkhof and Knox, 1996). Experimental data from tank experiments reproduce calculated chemical enhancement relatively well (i.e. Hoover and Berkshire, 1969; Liss, 1973; Wanninkhof and Knox, 1996; Degreif, 2006). The simple pH dependent fit derived from enhancement experiments in natural Baltic seawater published by Kuss and Schneider (2004) is not recommended for use, as influences of $T$, $S$ and $z$ are not considered.

The relevance of chemical enhancement for open-ocean $\text{CO}_2$ exchange is controversial as the calculation of $\alpha$ from wind speed over the ocean itself still bears considerable uncertainty. As $k$ in our experiments is measured directly, comparability to experimental results is quite straightforward.

Due to low temperatures during the Svalbard experiment, chemical enhancement of $\approx 3$ to $7\%$ is very low (Fig. 7). The influence of about three degree warming during the experiment in June 2010 is overall larger than the calculated difference arising from pH treatments (Fig. 4). Wrong pH-dependent chemical enhancement could produce artificial treatment effects in the carbon budget estimates especially in warm water ocean acidification studies. NCP estimates within this experiment by Silyakova et al. (2012) and Czerny et al. (2012a) at arctic temperatures are relatively unaffected by enhancement of this magnitude and possible uncertainties therein.

Evidence for a strong increase in chemical enhancement due to enzymatic catalysis by free carbonic anhydrases as suggested by Berger and Libby (1969) was not found in later experiments (Goldman and Dennett, 1983; Williams, 1983), but it might be interesting to reconsider this question in future mesocosm experiments.

The lack of empirical data coverage on chemical enhancement parameterisations in seawater poses the major quantitative uncertainty for NCP estimates based on $\text{CO}_2$ air–sea gas exchange using the presented method. Especially in setups were temperatures are high, the proportion of $\text{CO}_2$ exchange relying on theoretical considerations is high compared to the directly measured flux.
of \( \text{N}_2\text{O} \) (Dore and Karl, 1996; Santoro et al., 2010), but this was not yet directly observed. Physiological results (Goreau et al., 1980; Loescher et al., 2012) suggest possible \( \text{N}_2\text{O} \) production by nitrification in fully oxygenated waters to be very low. However, even \( \text{N}_2\text{O} \) production at relatively high surface layer nitrification rates, as found in upwelling regions (Rees et al., 2011), are orders of magnitudes too low to significantly bias the large fluxes caused by deliberate \( \text{N}_2\text{O} \) addition. The only known pathway of biological \( \text{N}_2\text{O} \) uptake as a reactive nitrogen species is by denitrifiers at anoxic conditions (\(<10\ \mu\text{mol O}_2\ \text{kg}^{-1}\) (Zumft, 1997; Zamora et al., 2012). Conditions favouring this process are unlikely to form in mesocosms and would result in a loss of the tracer (as \( \text{N}_2\text{O} \)) but not into utilisation of \( \text{N}_2\text{O} \) as a nitrogen source. Side-effects of \( \text{N}_2\text{O} \) addition on biological activity in mesocosm experiments can therefore not be expected. Remineralisation of detritus at the bottom of the mesocosm could possibly be a source of \( \text{N}_2\text{O} \). Conditions allowing for extensive remineralisation of accumulated organics inside pelagic mesocosms should thus be avoided. It is further strongly recommended to measure background natural \( \text{N}_2\text{O} \) concentrations preferably inside non-enriched experimental units, because \( \text{N}_2\text{O} \) is not considered as an inert gas.

### 3.4 Lateral gas exchange by diffusion through mesocosm wall material

Gas fluxes through the mesocosm walls can be calculated if temperature dependent permeability coefficients of the foil material and gases of interest are known.

Fluxes through the wall \( (F_{\text{wall}}) \) in mol d\(^{-1}\) can be derived using the equation:

\[
F_{\text{wall}} = \frac{D_t \cdot \Delta p \cdot A \cdot t}{z_m}.
\]  

Here \( D_t \) is the permeability coefficient at a given temperature in mol \( \cdot \mu\text{m} \cdot \text{atm}^{-1} \cdot \text{m}^{-2} \cdot \text{d}^{-1} \), \( \Delta p \) is the partial pressure difference between inside and outside in atm, \( A \) is the submerged surface of the mesocosm walls in m\(^2\), \( t \) is the duration in days and \( z_m \) is the thickness of the material in \( \mu\text{m} \). Turbulence of the media in and outside the mesocosm is not relevant to this diffusion gradient as permeation of the materials is generally orders of magnitude slower than removal and advection of gases in the media.

Estimates of lateral gas exchange for the Svalbard experiment were calculated based on permeability coefficients published for Desmopan\textsuperscript{®} 385, (Bayer). Desmopan\textsuperscript{®} 385 is the raw material of our bag foil (Walopur\textsuperscript{®}, Epurex Films). Direct measurements for Walopur\textsuperscript{®} are not available for \( \text{CO}_2 \) and \( \text{N}_2\text{O} \). Permeability for the specific temperatures was extrapolated.

For the experiments in the KOSMOS mesocosms, the fraction of the measured gas flux due to permeability of the bag material was maximal on the order of 1–2%. Fluxes are low because of the relatively thick foil (0.5 to 1 mm) at comparatively low temperatures. In the perspective of \( \text{CO}_2 \) gas exchange estimates for carbon mass balance it is generally not interesting whether \( \text{CO}_2 \) exchanges through the walls or via the water surface. However, differences between \( \text{N}_2\text{O} \) and \( \text{CO}_2 \) in the material specific permeability of the bags have the potential to cause systematic errors if exchange is largely through the foil and not with the atmosphere. Such differences seemed at first unlikely because of the general similarity of \( \text{N}_2\text{O} \) and \( \text{CO}_2 \) in diffusivity and solubility, but permeability specifications for Desmopan\textsuperscript{®} 385 suggest a considerably higher permeability for \( \text{N}_2\text{O} \) (27.1 and 51.7 mol \( \cdot \mu\text{m} \cdot \text{atm}^{-1} \cdot \text{m}^{-2} \cdot \text{d}^{-1} \) for \( \text{CO}_2 \) and \( \text{N}_2\text{O} \) at 25°C, respectively) (Bayer MaterialScience, TPU TechCentre). For the Svalbard experiment bias through lateral gas fluxes were not corrected, as the overall magnitude of these fluxes was negligible. The data basis in terms of permeability measurements would not have allowed for an exact correction of such bias. A set of permeability measurements at a relevant temperature range would improve gas exchange estimates especially at temperatures above 10°C. If thin foil is used for mesocosms, a material with good gas barrier properties should be chosen and exact permeabilities should be known for the gases of interest.

When \( k_{\text{N}_2\text{O}} \) is translated into transfer velocities of poorly water soluble gases, dissolution and adhesion of those gases in and on the plastic material could cause a lateral sink of these substances in addition to the permeability issue.

### 3.5 Sensibilities of the results towards uncertainties in measured variables

Sensitivities of the overall resulting \( \text{CO}_2 \) fluxes to uncertainties in the determination of the most important measured variables for the presented method were estimated (Table 1). Water temperatures are used on numerous occasions for the calculation of gas exchange rates, e.g. for the calculation of \( \text{CO}_2 \) from CT and TA\text{alk}, for Schmidt numbers, for solubility

[Table 1](#)

**Table 1: Sensitivities of the overall resulting \( \text{CO}_2 \) fluxes to uncertainties in the measured variables.**

- **Variable** | **Sensitivity** |
  --- | --- |
  Temperature |  |
  Partial pressure difference |  |
  Area |  |
  Time |  |
  Thickness |  |

**Note:** Sensitivities are calculated based on the equation:

\[
F = \frac{D \cdot \Delta p \cdot A \cdot t}{z_m}
\]  

where:

- \( F \) is the flux in mol \( \cdot \text{d}^{-1} \)
- \( D \) is the diffusion coefficient in mol \( \cdot \mu\text{m} \cdot \text{atm}^{-1} \cdot \text{m}^{-2} \cdot \text{d}^{-1} \)
- \( \Delta p \) is the partial pressure difference in atm
- \( A \) is the area in m\(^2\)
- \( t \) is the time in d
- \( z_m \) is the thickness in \( \mu\text{m} \)
and chemical enhancement. Errors in $k_{CO_2}$, in response to uncertainties in temperature, are mainly caused by the temperature dependence of $N_2O$ solubility. Errors in resulting $CO_2$ fluxes are largely balanced by errors in $CO_2$ solubility calculated using identical temperatures. The remaining sensitivity of 3% for 1°C appears to be relatively low in respect of usually very precise temperature measurements using current technology. It has to be kept in mind that gas exchange is a continuous process; therefore, measurement frequency should be adequate for sufficient description of relevant temperature changes during the entire duration of the experimental duration. At water temperatures above 10°C, chemical enhancement corrections become important so that precise temperature records gain additional relevance. Uncertainties in mesocosm volume or surface area translate directly into errors in calculated $CO_2$ fluxes (one to one%) when $k_{CO_2}$ measured in one mesocosm is applied to calculate gas exchange in a parallel mesocosm with different volume or surface area. A random uncertainty in $N_2O$ determination of 1.8% as denoted by Walter et al. (2006) would be averaged out due to the large number of fitted measurements. However, a hypothetical systematic underestimation of $N_2O$ by including outliers possibly caused by $N_2O$ losses from oversaturated samples would influence $k_{CO_2}$. The effect of systematic $N_2O$ underestimation was tested using an alternative fit including only upper end values. Resulting $CO_2$ fluxes differ by 0.7% in the beginning of the experiment when $N_2O$ concentrations were high and roughly equal fluxes calculated including all $N_2O$ measurements at the end of the experiment. Maximum uncertainties in $CO_2$ fluxes of 5% due to errors in the determination of air-sea $CO_2$ gradients are calculated on the basis of a maximum uncertainty of $±2 \mu mol \cdot kg^{-1}$ in CT as well as TAlk and an intermediate $CO_2$ gradient of $±400 \mu atm$.

Table 1. Sensitivities of the overall resulting $CO_2$ fluxes to uncertainties in the determination of the most important measured variables of the presented method. The effect of systematic $N_2O$ underestimation was tested using an alternative fit including only upper end values from the Svalbard dataset. The influence of errors in $CO_2$ gradient determination is denoted for an intermediate gradient of 400 $\mu atm$.

3.6 Processes driving gas exchange in mesocosms

The concentration of $N_2O$ ($CN_{2O}$) decreased quite steadily over the whole experimental period (Fig. 2). This indicates that $N_2O$ fluxes were controlled by the diffusion gradient to the atmosphere. Variable external forcing by wind or waves as commonly observed in natural environments was of minor importance. Wind measurements at Bellevaja station at 10 m above sea level ($U_{10}$) reported velocities of up to 5 m s$^{-1}$ during the experiment (Fig. 6). The water surface of the mesocosms, however, is sheltered from direct wind shear by the two meter high plastic walls of the bag (Fig. 1; Riebesell et al., 2012).

Fetch, the distance wind could act on the water surface, was dependent on wind direction (maximum of ~10 nm in the Kongsfjorden). Waves that were able to propagate through the mesocosms (significant wave height ($H_{1/3}$) up to ~0.8 m) were only observed on the mooring site off the fjord from southeast, the most exposed wind direction. Enhanced gas exchange during the days with waves could not be resolved by our measurements. However, $CO_2$ gas exchange inside the mesocosms was measured to be constantly about three times higher than calculated flux at zero wind as performed by Delille et al. (2005) (Fig. 7, stagnant film thickness calculated according to Smith, 1985, chemical enhancement according to Hoover and Berkshire, 1969).

Applying a quadratic wind dependent function (Wanninkhof, 1992) at constant wind speed of 3.15 m s$^{-1}$, resulting fluxes are very close to our empirical estimate over the whole period. Measured $U_{10}$ wind speeds at the experimental site were generally lower than this (mean 2.1 m s$^{-1}$), and accordingly calculated mean air--sea gas exchange was also lower outside in the fjord than inside the mesocosms. Compared to relevant open-ocean gas transfer, estimated mesocosm $CO_2$ transfer velocities between ~1.9 to 2.5 cm h$^{-1}$ in the Svalbard experiment are low. They are within a gray zone of baseline gas exchange where buoyancy fluxes and chemical enhancement contribute largely to gas exchange so that purely wind dependent parameterisations are not applicable (Wanninkhof et al., 2009). Additional factors can be argued to be driving gas exchange in mesocosms compared to open waters. Rinsing of the plastic walls when waves are propagating through the setup presumably leads to enhanced air-sea surface renewal compared to open water. Slight temperature changes in the surrounding water mass were immediately
3.7 Mesocosm proportions

Transfer velocities ($k$) in other mesocosm setups deployed in more sheltered surroundings, standing on land or inside climate controlled rooms might be lower or higher, depending on methodology used for sampling, temperature control, active mixing and gas specific permeability of the mesocosm material. Even more important than these influences on $k$, is the ratio between the mesocosm volume and its surface area ($A/V$), when exchange rates are normalised to units of water (kg$^{-1}$ or L$^{-1}$). In an exemplary 15 m deep KOSMOS mesocosm (Fig. 1), holding ~45 m$^3$ of water, CO$_2$ gas exchange over 3.14 m$^2$ ($A/V = 0.07$) surface area is causing relatively moderate changes in aquatic concentrations despite large diffusion gradients (Fig. 3). Taking the example of the Kiel indoor mesocosm (Fig. 8a) of about 1.4 m$^3$ at 2 m$^2$ surface ($A/V = 1.4$), concentration change in response to the same gas exchange flux is 20 times faster. Additionally, air-sea gas exchange velocities are accelerated by continuous active mixing, necessary to keep plankton organisms in suspension (Fig. 8a). While after 20 days ~50% of the N$_2$O added was still present during the Svalbard study (Fig. 1), the same tracer concentration was virtually gone after five days in the shallow indoor mesocosm (Fig. 8b) in the uncovered configuration. Here, inorganic carbon uptake by phytoplankton can be rapidly compensated by ingassing of CO$_2$ from the atmosphere. Ocean acidification experiments in setups with $A/V$

heating or cooling the bags (Fig. 5), this probably caused considerably enhanced buoyancy fluxes that kept the experimental units relatively homogenous throughout the experiment. Last but not least, the extensive daily sampling with water samplers and probes contributed to gas exchange by active perturbation of the mesocosm surface.

Fig. 6. Wind speed and direction during the course of the experiment, measured at 10 m height at Bøyelva station, Ny Alesund. Waves (up to $H_{1/3} = 0.8$ m) were observed at the mooring site during time intervals indicated by shaded areas, when relatively strong wind was blowing along the fjord from southeast.

Fig. 7. Comparison of different approaches to estimate CO$_2$ air-sea gas exchange. Daily ingassing rates in the low CO$_2$ control treatment (average ~ 180 µatm) are shown in blue, while outgassing from the highest CO$_2$ treatment (average ~ 1085 µatm) is red. Filled symbols are estimates from the N$_2$O tracer approach, circles (●) for chemical enhanced flux and triangles (▲) for non chemical enhanced flux. Open squares (□) are an estimate using a quadratic wind dependent function according to Wanninkhof (1992) at a constant wind speed of 3.15 m s$^{-1}$, chosen to match the N$_2$O results. Open circles (○) are a chemically enhanced zero wind speed output, according to Smith (1985), while open triangles (△) are the same estimate without chemical enhancement.

similar to the Kiel indoor mesocosm would lose their treatment CO$_2$ within a few days. To maintain treatment levels in such shallow experiments, continuous measurement and control technology can be used (see e.g. Widdicombe and Needham, 2007). Resulting controlled treatment levels are beneficial when physiological questions are investigated. However, CO$_2$ drawdown does not occur, and therefore DIC concentration change cannot be used to calculate NCP. Another option is to artificially decrease the surface area by covering the mesocosm with a low permeability transparent film. For comparison 50 nmol kg$^{-1}$ N$_2$O was added to two Kiel indoor mesocosms, one in an uncovered configuration and one covered with a transparent floating foil to reduce surface in contact with the atmosphere (Fig. 8a). Both mesocosms were stirred at the same speed; samples were drawn using a tube. The thin polyurethane foil mounted on a light frame and floating on the surface, efficiently minimised air-sea gas exchange (Fig. 8b). If covers are used, reducing the surface area to a minimum, it has to be considered that the remaining open surface should be equally large. As the working principle of this approach is to minimise surface area, it can be assumed to be very sensible to the size of the remaining interface (leaks). Therefore, air-sea gas exchange should be measured in all experimental units to check for reproducibility of results.

Biogeosciences, 10, 1379–1390, 2013
4 Conclusion and outlook

Direct measurement of N$_2$O air–sea gas exchange can be used to estimate accurate CO$_2$ fluxes in various mesocosm setups, whereas common wind dependent parameterisations for air–sea gas exchange cannot be adapted to mesocosm conditions and their application is therefore prone to systematic errors. Within the mesocosm low energy physical surrounding, N$_2$O gas exchange measurements allow for direct estimation of CO$_2$ fluxes with uncertainties far below open-ocean dual tracer measurements due to a known, constant water volume. Measured transfer velocities are within the range of zero wind open-ocean baseline velocities assumed to be dominated by chemical enhancement and buoyancy fluxes (Wanninkhof et al., 2009). The influence of sea surface microlayers of surface active organic molecules is discussed to be responsible for large discrepancies in gas exchange between productive coastal waters and open-ocean conditions (Frew, 1997; Kock et al., 2012). The decrease in open-ocean k by 20–50%, due to surfactants smoothening wind effects on the water surface (Tsai and Liu, 2003), can be expected to be of minor relevance to mesocosm gas exchange where wind stress is not the dominating energy input. The effect of these surfactants, possibly produced in high amounts during phytoplankton blooms in mesocosms, is difficult to include in theoretical calculations, but is inherently included in our direct measurements. Future mesocosm experiments combining the close observation of biological, chemical and physical processes might offer the opportunity to bring more light into origin and composition of organic surface microlayers.

The application of gas exchange measurements for calculation of NCP inside the mesocosm delivered satisfying results. Of the four community production estimates published for the Svalbard 2010 experiment, NCP calculated from changes in dissolved inorganic carbon corrected for air–sea gas exchange (Czerny et al., 2012a; Silyakova et al., 2012) seems to be quantitatively most plausible. Although overall quantity compares relatively well with results from oxygen and in situ $^{13}$C– primary production estimates (Tanaka et al., 2013; de Kluijver et al., 2013), comparability to $^{14}$C incubation data presented by Engel et al. (2012) is weak. Much higher $^{14}$C fixation rates can be plausibly explained by the shallow (~1 m) incubation depth, while oxygen incubations obviously experienced more intermediate light and temperature conditions at ~4 m depth. $^{13}$C tracer incorporation measurements inside the mesocosm deliver results representative for the entire mesocosm but only for a period before organic matter approached saturation with the tracer (de Kluijver et al., 2013). Rates measured in side experiments are more useful to compare community production between the treatments rather than giving quantitative cumulative estimates for in situ carbon uptake (see discussion in Engel et al., 2012). As incubations were performed only at one depth, it is impossible to integrate these data over time and depth in respect of variable light and temperature gradients. Summing up incubation results to achieve cumulative estimates could lead to further error propagation, whereas NCP calculated from in situ inorganic carbon measurements is per se cumulative and propagation of single measurement errors cannot occur.

Further development of the N$_2$O tracer concept is focussed on using it not only to determine air–sea gas exchange in stratified mesocosms, but also to estimate diapycnal mixing between surface layer and deep water inside mesocosms. For this purpose, N$_2$O gradients developing over time will be correlated to high resolution profiles of oxygen, pH and salinity, measured with CTD sensors. Especially in temperate turbid waters, mesocosm NCP is mostly not restricted by mesocosm length but by light penetration. The phototrophic surface layer communicates to some extent with a more nutrient rich deep layer where heterotrophic processes dominate. Budgeting these more naturally structured mesocosms is not only an interesting challenge, but will also introduce new ecological aspects connected to upward and downward elemental fluxes into the biogeochemical interpretation of the mesocosm system.

Sediment sample processing

by Jan Czerny, Tim Boxhammer, Klaus von Bröckel, Andrea Ludwig, and Ulf Riebesell
Sediment sample processing

Similar to many previous mesocosm setups, KOSMOS prior to 2010 used sediment traps placed within the mesocosm to quantify sinking material. Sediment data were found to be of a more qualitative than quantitative nature. Within published experiments, sinking fluxes were calculated on the basis of those data often only when combining measured elemental composition with mass balance calculations based on water column data (Riebesell et al., 2008; Vadstein et al., 2012). After analysing the first sediment dataset from the 2009 Baltic Sea experiment, problems in gathering qualitative data on sinking fluxes within the mesocosms became evident. Daily measured sediment quantities as well as elemental composition of the material were strongly variable, impeding publication of the dataset. A correlation to parallel water column data could hardly be detected. Variability was presumably caused by resuspension of already settled material and uneven distribution of sinking matter within the mesocosm. Sinking flux measurements were improved on several stages of the protocol for the 2010 Svalbard experiment. Firstly, the collection of the sinking material was expanded from sampling a sub-unit of the bottom surface to a sediment trap covering the entire bottom surface. Secondly, the sampling method was improved in terms of technical reliability, sampling speed and most importantly in preserving the integrity of the sediment particles. Therefore the diameter of the extraction hoses was enlarged (from 5 to 10 mm) and the battery driven peristaltic pump was replaced by a hand operated vacuum system. This procedure keeps aggregates fairly intact instead of dispersing the sediment material within the attendant water. Blurry sediment samples with large parts of the aggregates dispersed can only be sampled by filtration techniques, impracticable at prevailing particle densities. Consequently, as a third innovation, the sample preservation and sub-sampling method was changed from a filtration technique as applied to water samples to a centrifugation technique taking advantage of particles sinking.

The aim of the sediment processing technique, developed for the Svalbard 2010 experiment, was to quantitatively extract and homogenize all settling particles sampled from the mesocosm for representative sub-sampling. Even the largest sinking items e.g. dead juvenile fish are represented in all homogenized sub-samples analysed for this sampling day, instead of producing an outlier in one of the measurements.
Figure 2.1. Processing of the sediment samples. a) Extraction of settled material in regular intervals, b) settling and decantation, c) centrifugation d) lyophilisation, e) embrittlement, f) grinding, g) warming, h) storage.

Sedimented material collecting in the funnel tip at the bottom of KOSMOS mesocosms is extracted by applying a hand pumped vacuum on a 5 L glass bottle connected to a silicon rubber hose reaching from the sea surface down to the funnel tip (Fig. 2.1a). The bottles with sediment material and attendant water are kept in a cool room for about two hours to settle, allowing extraction of the clear supernatant. In later experiments, a solution of FeCl₃ together with NaOH was used to speed up aggregation by precipitating the small fraction of fine particles within the water phase (Fig. 2.1b). The dense material left is centrifuged to a compact pellet (Fig. 2.1c) and stored at -20 °C. Pellets are later dried by lyophilisation, avoiding evaporation or decay of sensitive organic compounds (Fig. 2.1d). Prior to grinding, lipids and tough components within the dried material are embritted by cooling with liquid nitrogen (Fig. 2.1e). A custom-built stainless steel ball mill is used for the grinding process (Fig. 2.1f). After warming to room temperature, the fine powder is transferred into storage vessels that are kept cold and dark (Fig. 2.1g, h). Elemental analyses for carbon, nitrogen, phosphorus and biogenic silica on sub-samples of the ground material show high reproducibility similar to homogenous reference material (Fig. 2.2).

There is usually sufficient material available for test measurements and replication, and even repetition of entire analytic runs. After test analyses, sample size is adjusted to the required range for any specific analytical method. For the Svalbard 2010 experiment, ground material was analysed for inorganic and organic carbon, as well as total nitrogen, phosphorous and biogenic silica (Czerny et al., 2013). Furthermore, δ¹³C elemental composition of specific fatty acids in the sediment was analysed to track the contribution of different food web components to sinking.
flux after deliberate $^{13}$C enrichment in the water column (de Kluijver et al., 2013). HPLC (High Pressure Liquid Chromatography) analyses of phytopigments showed that pigments were well preserved allowing analyses of the contribution of specific phytoplankton taxa to sediment flux (unpublished results).

Figure 2.2. Variation in carbon of replicate carbon measurements of five homogenised sediment samples (black dots) featuring carbon contents between 13 and 30 $\mu$mol*mg$^{-1}$C. Open circles represent five replicate measurements of acetanilide used as homogeneous reference material. Measurement of each ~4mg sample and 0.4mg acetanilide in tin capsules was carried out using an elemental analyser (EuroVektor EA) according to Sharp (1974).

Abstract. Recent studies on the impacts of ocean acidification on pelagic communities have identified changes in carbon to nutrient dynamics with related shifts in elemental stoichiometry. In principle, mesocosm experiments provide the opportunity of determining temporal dynamics of all relevant carbon and nutrient pools and, thus, calculating elemental budgets. In practice, attempts to budget mesocosm enclosures are often hampered by uncertainties in some of the measured pools and fluxes, in particular due to uncertainties in constraining air-sea gas exchange, particle sinking, and wall growth. In an Arctic mesocosm study on ocean acidification applying KOSMOS (Kiel Off-Shore Mesocosms for future Ocean Simulation), all relevant element pools and fluxes of carbon, nitrogen and phosphorus were measured, using an improved experimental design intended to narrow down the mentioned uncertainties. Water-column concentrations of particulate and dissolved organic and inorganic material were measured daily. New approaches for quantitative estimates of material sinking to the bottom of the mesocosms and gas exchange in 48 h temporal resolution as well as estimates of wall growth were developed to close the gaps in element budgets. However, losses elements from the budgets into a sum of insufficiently determined pools were detected, and are principally unavoidable in mesocosm investigation. The comparison of variability patterns of all single measured datasets revealed analytic precision to be the main issue in determination of budgets. Uncertainties in dissolved organic carbon (DOC), nitrogen (DON) and particulate organic phosphorus (POP) were much higher than the summed error in determination of the same elements in all other pools. With estimates provided for all other major elemental pools, mass balance calculations could be used to infer the temporal development of DOC, DON and POP pools.

Future elevated pCO\textsubscript{2} was found to enhance net autotrophic community carbon uptake in two of the three experimental phases but did not significantly affect particle elemental composition. Enhanced carbon consumption appears to result in accumulation of dissolved organic carbon under nutrient-recycling summer conditions. This carbon overconsumption effect becomes evident from mass balance calculations, but was too small to be resolved by direct measurements of dissolved organic matter. Faster nutrient uptake by comparatively small algae at high CO\textsubscript{2} after nutrient addition resulted in reduced production rates under future ocean CO\textsubscript{2} conditions at the end of the experiment. This CO\textsubscript{2} mediated shift towards smaller phytoplankton and enhanced cycling of dissolved matter restricted the development of larger phytoplankton, thus pushing the system towards a retention type food chain with overall negative effects on export potential.
I Introduction

Increasing atmospheric CO₂ concentration is the major man-made geochemical perturbation characterising the anthropocene (Doney, 2010; Revelle and Suess, 1957). Atmospheric CO₂ partial pressure already increased by 40% since the beginning of industrialisation, while rates of CO₂ emissions are continuing to increase beyond most modelled worst-case scenarios, e.g. SRES (Special Report on Emissions Scenarios) A1FI (Meehl et al., 2007; Friedlingstein et al., 2010). Correlations of increasing CO₂ concentrations to global warming are predictable and documented by current measurements as well as in the geological record (Hansen et al., 2006; Petit et al., 1999). About one third of the currently emitted CO₂ is dissolving in the world oceans, serving as a buffer for global climate change (Sabine et al., 2004). However, most of the absorbed CO₂ is accumulating in the surface ocean, separated from deep water masses by thermal stratification, which will further strengthen under global warming. In surface waters, ocean carbonation (increasing CO₂ concentrations) and consequential ocean acidification (decreasing pH) are affecting marine organisms, thereby modulating ecosystem functioning (Riebesell et al., 2009). A predominant geochemical function of the marine planktonic ecosystem is the formation of organic matter from dissolved CO₂. Sinking of this organic matter, transporting carbon across barriers of physical mixing into the ocean interior is referred to as the biological carbon pump (Sarmiento and Le Quéré, 1996; Volk and Hoffert, 1985). Increasing temperatures affect the ocean’s function as a physical CO₂ sink, but acidification and carbonation are likely to impact also future biological carbon sequestration (Riebesell and Tortell, 2011; Gruber, 2011).

The Arctic Ocean plays a key role in sequestration of anthropogenic carbon for several reasons. From the physical perspective, high solubility of CO₂ in cold water leads to a high physical sequestration potential of anthropogenic CO₂ in areas of deep water formation. From the biological perspective, nutrient supply to the surface layer during winter deep mixing can promote pulses of high productivity with a large potential for carbon export via the biological pump (Lutz et al., 2007). Whether there is a net release or sequestration of atmospheric carbon depends on the carbon to nutrient ratio and sinking rate of the material exported after a mixing event. These properties are known to be highly variable, depending on food web structure. Deep sedimentation events in the Arctic Ocean may occur when fast sinking particles are formed, i.e. through coagulation of diatom blooms (Klaas and Archer, 2002) or by pteropods and their sticky nets (Bathmann et al., 1991). But efficient recycling of material by a surface layer retention food web may keep export at a low level (von Bodungen et al., 1995). Ocean warming and acidification are expected to impact ecosystems particularly in Arctic regions. Sea-surface warming will likely result in elevated primary production due to a reduction of sea ice cover and the shoaling of mixed layer depth in the light limited Arctic. Estimates for these effects of sea-surface warming are implemented in various global carbon flux models (Bopp et al., 2001; Sarmiento et al., 2004; Schmittner et al., 2008), whereas effects of changing seawater carbonate chemistry and pH on Arctic community export production are more difficult to quantify.

Ocean acidification and carbonation have the potential to directly affect ecosystem functioning in numerous ways. Of those, the adverse effect of future decreasing pH and carbonate ion concentrations on marine calcification is the most investigated mechanism (Riebesell, 2004; Fabry et al., 2008). Pteropods and foraminifera, the only calcifying organisms of significant relevance to the high Arctic pelagic ecosystem examined, were found to be very sensitive to ocean acidification (Comeau et al., 2009; Lombard et al., 2010; Lischka et al., 2011). Carbonation is also found to directly affect phototrophic carbon fixation of cultured marine phytoplankton and natural plankton assemblages (Riebesell and Tortell, 2011). In most studies, elevated CO₂ is reported to enhance carbon fixation, however, CO₂ affinity differs between different algal taxonomic groups (Reinfelder, 2011).

In addition to effects of ocean carbonation on primary production, bacterial enzymatic rates were found to be directly affected by decreasing seawater pH (Piontek et al., 2010). Moreover, chemical speciation of potentially limiting micronutrients seems to be pH dependent in the range of projected ocean acidification (Millero et al., 2009).

Increased inorganic carbon consumption in response to elevated pCO₂ was already found in incubated natural plankton communities of the North Atlantic (Hein and Sand-Jensen, 1997) and in mesocosm studies in a Norwegian Fjord compiled by Riebesell et al. (2008). CO₂ induced overconsumption of carbon that was presumably exuded by phytoplankton cells in form of organic matter, which was measured as transparent exopolymer particles (TEP). The sticky carbon-rich TEP aggregated with other particles in the water column, thereby potentially increasing carbon export (Engel, 2002; Engel et al., 2004a). Enrichment of carbon relative to nitrogen in the exported matter would cause a substantial increase in the total amount of carbon sequestered in the future ocean (Oschlies, 2009).

This study investigates the response of a natural Arctic plankton community, including all trophic levels from bacteria to millimetre-sized zooplankton, to changes in seawater carbonate chemistry. Treatment levels ranged from ~180 µatm CO₂ as prevailing during the early summer situation in the beginning of the experiment, over present day and year 2100 atmospheric projections to extreme values of up to 1420 µatm CO₂. Using tracer gas exchange measurements and quantitative high resolution sediment sampling, we are able to present daily budget calculations for carbon, nitrogen, and phosphorus in all mesocosms. Mass balance calculations were used to crosscheck measured trends and to provide a quantitative evaluation of biogeochemical
fluxes. A "Pool X" representing the carbon not reproducibly measured on a daily basis will be discussed to evaluate the performance of the applied methods and to identify problematic measurement parameters. Those parameters (DOC, DON and POP) will be then estimated based on mass balance calculations. CO₂-induced changes in carbon fluxes within the water column, towards export and in exchange with the atmosphere are detected using correlation statistics. The presented dataset focuses on carbon fixation and export, but is however too unspecific to provide detailed insights into ecosystem functioning. Based on the presented mass balance, elemental cycling and export is discussed with reference to publications on the same experiment, putting biogeochemistry in the context of the observed plankton community composition.

2 Material and methods

2.1 Experimental set-up

Nine KOSMOS (Kiel Off-Shore Mesocosms for future Ocean Simulation) mesocosms were moored in the Kongsfjord, Svalbard (78°56.2' N, 11°53.6' E). The enclosures were cylindrical polyurethane bags 2 m in diameter, 17 m long and reaching ~ 15 m deep into the water. The bags were supported by a stainless steel and glass fibre flotation frame and weighted at the bottom with steel rings closable with polycarbonate watertight shutters. The bags reaching 2 m above the water surface were open to the atmosphere. A spiked roof was mounted at the top to prevent birds from resting on the structures and introducing nutrients into the system (Fig. 1). The fjord water, enclosed by lowering of the bags on the 31 May 2010 (t-7), had a salinity of about 34. The mesocosms contained a natural plankton community, though larger plankton and nekton were excluded using a net (3mm mesh size) covering the upper and lower opening of the mesocosm during filling. After simultaneous watertight closure of the systems on t-5, flotation rings (Fig. 1) were released from the bottom shutters to buoy upwards, unfolding funnel-type sediment traps of 2 m height. This upper ring of the funnel was of the same diameter as the bag (2 m), therefore touching it on all sides. The rather tight fit of the funnel was chosen to minimise sediment losses at the sides but resulted in ~ 4.5 m³ of water below the funnel, which had only limited exchange with the bulk of enclosed water above the funnel. Depending on water/bag movement, water exchange between mesocosms and this "dead volume" happened on a timescale of days. Sediment lost into this dead volume before reliable budgets could be calculated.

2.2 Manipulation

The water volume enclosed in flexible wall mesocosms can vary by some percent and was therefore determined using small additions of a calibrated NaCl solution as a tracer (~ 1 mL L⁻¹ = 0.2 g L⁻¹). Salinity measurements allowed calculation of the enclosed water volume of each individual mesocosm with uncertainties of less than 1% (Czerny et al., 2013a). Measurements were performed twice, on t-4 and t4, because of considerable uncertainties in salinity measured before the first tracer addition on t-4. Measured volumes were consulted to plan further manipulation steps and to calculate elemental budgets. From t-1 to t4, CO₂ enriched filtered seawater solution was added to achieve eight CO₂ treatments between 185 and 1420 µatm CO₂, spanning a pH gradient from 8.31 to 7.51 (measured after mixing with the dead volume on t8). The two ~ 180 µmol CO₂ "control" mesocosms were undersaturated with respect to atmospheric CO₂ at the time the mesocosms were deployed and were blank manipulated using 55 µm filtered fjord water. All mesocosms were enriched with N₂O as a gas exchange tracer to a final concentration of ~ 50 nmol kg⁻¹ on t4, when the second salt addition was performed. Before sampling on t13, a seawater-based mixed nutrient solution, calculated for the volumes of each single mesocosm, was added to establish equal concentrations of NO₃⁻ (5 µmol kg⁻¹), PO₄³⁻ (0.31 µmol kg⁻¹) and SiO₂⁴⁻ (2.5 µmol kg⁻¹) in all mesocosms. All additions were performed using the "Spider" injection system (Fig. 1a). For a more detailed description of the mesocosm manipulation technique see Riebesell et al. (2013). And for a description of inorganic nutrient dynamics see Schulz et al. (2013).

2.3 Sampling

The entire experiment from filling (t-7) to the last sampling of the mesocosms (t31) lasted 39 days. Sampling started at t-3, two days prior to the beginning of the CO₂ manipulation and lasted until t30 for most variables presented here. Daily water sampling for dissolved and particulate matter (representing total inorganic carbon (CT), dissolved inorganic nitrogen (DIN) and phosphorus (DIP), dissolved organic carbon (DOC), nitrogen (DON) and phosphorus (DOP), as well as particulate carbon (PC), organic nitrogen (PON) and phosphorus (POP)) was between 09:00 and 11:00 LT (local time) from boats. Samples were taken using 5 L depth-integrating
2.4 Measurement procedures

Aliquots of water samples for analyses of chlorophyll a (Chl a; 250–500 mL), PC, PON and POP (400–500 mL) were filtered under low vacuum (200 mbar) on glass fibre filters (Whatman GF/F 25 mm Ø, pre-combusted at 450 °C for 5 h) and stored frozen at −20 °C. Chl a was determined fluorometrically according to Welschmeyer (1994) using a Turner fluorometer 10-AU (Turner BioSystems). Quantification of PC and PON was carried out using an elemental analyser (EuroVektor EA) according to Sharp (1974). POP and BSI was determined following the method by Hansen and Koroleff in Grasshoff et al. (1983). For POP this method was modified to the measurement of samples on glass fibre filters. Here, particulate matter was completely oxidised by heating the filters in 50 mL glass bottles with 40 mL of purified water and the reagent Oxisolv (Merck) in a pressure cooker. Solutions were measured colorimetrically on a Hitachi U 2000 spectrophotometer. DOC, DON and DOP were determined from filtered (Whatman GF/F 25 mm Ø, pre-combusted at 450 °C for 5 h) water samples. DOC was analysed on a Shimadzu TOCVCN using the HTCO (high-temperature catalytic oxidation) method (Qian and Mopper, 1996); for details see Engel et al. (2013). DON and DOP were oxidised as described for POP and subsequently measured as inorganic nutrients, for nitrate (NO$_3$), nitrite (NO$_2$) and phosphate (PO$_4^{3-}$) according to Hansen and Koroleff (1999), and for ammonia (NH$_4^+$) according to Holmes et al. (1999). The sum of NO$_3^-$, NO$_2^-$ and NH$_4^+$ is presented as dissolved inorganic nitrogen (DIN). For a more detailed description of particulate matter (POM) and dissolved organic matter (DOM) and inorganic matter (DIM) analyses see Schulz et al. (2013). CT was determined via coulometric titration using a SOMMA (Single Operator Multiparameter Metabolic Analyser) system, and TALK via potentiometric titration (Dickson, 1981). CO$_2$ concentrations, partial pressures and pH (total scale) were calculated from CT and TALK measurements with the program CO2SYS by Lewis and Wallace (1998). For more details on carbonate chemistry see Bellery et al. (2012).

Frozen sediment pellets were freeze dried at a pressure of ~50 mbar for 1–2 days without additional heat input until room temperature was reached. Subsequently, the dried sediment was ground in a stainless steel ball mill at low temperatures using liquid nitrogen to cool the sample before grinding. Sub-samples adjusted to the analytic measurement range (5–10 mg) were weighed on a precision scale. Analyses of particulate matter were performed as described above for PC, PON, POP and BSI on filters. 20 to 30 mL sub-samples of the sediment suspension, as well as samples from vertical net hauls were analysed for zooplankton composition, abundance and biomass under a dissecting microscope. At the same time, sediment samples were also inspected for general composition (detritus and phytoplankton). Zooplankton was sorted into tin cups for bulk carbon and nitrogen analyses as...
described above for water-column PC and PON. For more details on zooplankton analyses see Niehoff et al. (2013).

2.5 CO₂ gas exchange estimate

Daily air–sea gas exchange velocities (k) were estimated using N₂O as a gas tracer. Calculations were based on fitted concentration decrease inside the mesocosm in relation to calculated equilibrium concentrations estimated using water T/S and atmospheric N₂O concentrations monitored on Zeppelin Mountain (~4 km distance from the experimental site). Daily CO₂ fluxes were calculated using k (adapted to CO₂ using published Schmidt numbers) together with CO₂ air–sea diffusion gradients. CO₂ gradients were derived from bulk aquatic CO₂ concentrations calculated from CT and AT as well as estimated using bulk water T/S and atmospheric CO₂ concentrations recorded on Zeppelin Mountain. Corrections for chemical enhancement by Hoover and Berkshire (1969) were applied. For a detailed discussion on gas exchange measurements in mesocosms including complete references on used constants see Czemy et al. (2013b). Zeppelin Mountain atmospheric data were provided by Thomas Conway from the NOAA Carbon Cycles Gases Group in Boulder, US, and Johan Ström from ITM (Department of Applied Environmental Science), Stockholm University, Sweden; atmospheric N₂O and CO₂ measurements, respectively.

2.6 Wall growth estimate

After sampling on the last day of the experiment (t30), a special brush (Fig. 1b) was used to mechanically remove and suspend biomass growing on the inner surface of the mesocosm bag as described in Riebesell et al. (2013). Detached biomass was then quantified by POM measurements of the water column before and right after brushing as described above.

2.7 Data presentation

Budget calculations for carbon (C), nitrogen (N) and phosphorus (P) are based on changes in pool sizes over time (Δpool) relative to a reference point in time. The addition of CO₂ enriched seawater caused major changes in the CT budget that could only be precisely quantified by direct measurements of CT inside the mesocosms. The earliest reference points for CT budgets were measured after complete mixing of the water column above and below the sediment traps. In the high CO₂ mesocosms this took until t8, while CT values were found to be stable in the non-manipulated control and in some low CO₂ mesocosms earlier. N and P budgets were calculated starting on t13, after inorganic nutrients were added. As a reference value for ΔDIN and ΔDIP from t13 onwards, concentrations measured on t12 plus the known amounts of added inorganic nutrients were used. This particular reference point was chosen because, in this way, budget calculation could be started on the day of nutrient addition, e.g., before the added nutrients were fully mixed into the dead volume below the sediment traps (see Sect. 2.1). For dissolved and particulate organic matter, starting values (t0, t8, t13, t20) for the analysed phases were obtained by averaging measured concentrations of the respective days with those of the days before and after. As measurement precision for inorganic matter is much higher than for organic material, averaging over three consecutive days was not needed and the concentrations of dissolved inorganic pools measured on the reference days were used as starting values.

Measured changes in inorganic matter that cannot be accounted for by the combined changes in pools of dissolved and particulate organic matter, cumulative gas exchange and sedimentation were assigned as "Pool X", representing a combination of measurement errors and the following pools unaccounted for in daily sampling: (1) a small amount of sedimented material accumulated in the space surrounding the sediment trap (dead volume) that could not be sampled. (2) A biofilm growing on the mesocosm walls became visible towards the end of the experiment. The size of this pool was estimated from water-column measurements taken immediately before and after brushing the mesocosm walls. (3) Fast-swimming zooplankton such as copepods were not quantitatively sampled with the depth-integrating sampler and are therefore not adequately represented in PC/PON/POP measurements. Biomass of zooplankton larger than 55 µm was estimated by weekly Apstein net hauls. Estimates for these three contributors to Pool X within the three phases of the experiment are based on theoretical considerations combined with data on wall growth, zooplankton, and sediments (Table 1). Due to a rather constant elemental composition of particulate matter close to Redfield ratios of 106/16/1, those uncertainties in nitrogen and phosphorus are proportionally smaller than presented uncertainties in carbon (data not shown).

Corrections for the effect of water evaporation on dissolved and particulate matter concentrations as well as corrections for the effect of sampling-derived volume decrease on the calculation of air–sea and sediment fluxes were not included to keep calculations traceable. With a range of ~0.2% and ~1%, respectively, over the whole experiment, corrections are below the detection limit of most of the applied methods. Moreover, the effects of small changes in water volume would be identical in all mesocosms.

Changes in Pool X (ΔX_{\text{C/N/P}}) were calculated for the three phases of the experiment as the summed amount of changes in all major pools as:

\[ \Delta X_c = \Delta CT + \Delta GX + \Delta PC + \Delta DOC + \Delta \text{Sed}_c, \]  
\[ \Delta X_N = \Delta \text{DIN} + \Delta \text{PON} + \Delta \text{DON} + \Delta \text{Sed}_n, \]  
\[ \Delta X_P = \Delta \text{DIP} + \Delta \text{POP} + \Delta \text{DOP} + \Delta \text{Sed}_p. \]  

www.biogeosciences.net/10/3109/2013/

Biogeosciences, 10, 3109–3125, 2013
With $\Delta CT =$ change in total inorganic carbon concentrations, $\Delta GX =$ cumulative exchange of carbon with the atmosphere (flux in = negative/out = positive), $\Delta PC =$ change in total particulate carbon concentrations, $\Delta DOC =$ change in dissolved organic carbon concentrations, $\Delta Sed =$ cumulative amounts of the respective element found in the sediment trap, $\Delta DIN =$ change in dissolved inorganic nitrogen concentrations, $\Delta PON =$ change in particulate organic nitrogen concentrations, $\Delta DON =$ change in dissolved organic nitrogen concentrations, $\Delta DIP =$ change in dissolved inorganic phosphorus concentrations, $\Delta POP =$ change in particulate organic phosphorus concentrations, $\Delta SedP =$ change in dissolved organic phosphorus concentrations.

Pool X should be ideally zero as changes in one of its components should always be balanced by changes in one or several others. To trace back the source of changes in Pool X, regression analyses were performed, thus testing the degree of variance in all daily Pool X within each phase to be explained by changes in each of the single components on corresponding days (Fig. 2, Table 2). In this way, unexplained variability in measured concentrations of DOC, DON and POP were found to explain most of the variability in Pool X for carbon, nitrogen and phosphorus, respectively. Therefore mass balance calculations were used to estimate possible changes in DOC, DON and POP on the basis of all other budget components. Those estimates are presented as $DOC_{calc}, DON_{calc}$ and $POP_{calc}$. Bias in these estimates, composed of summed measurement uncertainties and errors in the combined variables as well as undetermined pools (Table 1), is considerably lower than measurement errors in DOC, DON and POP.

Thus, estimates of $DOC_{calc}, DON_{calc}$ and $POP_{calc}$ were calculated using mass balances according to the following equations:

$$\Delta DOC_{calc} = \Delta CT + \Delta GX + \Delta PC + \Delta Sed_{C},$$

$$\Delta DON_{calc} = \Delta DIN + \Delta PON + \Delta Sed_{N},$$

$$\Delta POP_{calc} = \Delta DIP + \Delta DOP + \Delta Sed_{P}.$$

As sediment traps were sampled every other day, measured values were linearly interpolated for days in between. Also missing data points of other parameters were linearly interpolated between preceding and subsequent measurements. This applies for DON and DOP of all mesocosms on t16 and t19 and for 8 single data points of DOC.

### 2.8 Statistics

The set-up with 8 different CO2 treatment levels and no replication of treated mesocosms was designed for regression analyses. Delta values of all tested phases are calculated using the first day of the respective phase as a reference point. Means of changes in measurement parameters ($\Delta$values) of single mesocosms during the three phases of the experiment were plotted against mean $pCO_2$ in the mesocosms during that specific phase. The null hypothesis that the overall slope is zero and that there is no linear relationship between treatment $pCO_2$ and mean $\Delta$ values was statistically tested with an $F$ test. Data satisfied assumptions for normal distribution, as confirmed by a Shapiro–Wilks test. Analyses were performed using the program Statistica 6.0 (StatSoft Inc., Tulsa, USA). The same statistical procedure was applied to regression of Pool X to single budget components.

### Table 1. Estimates for the contribution of undetermined carbon pools (or not daily determined pools) to Pool X or $\Delta DOC_{calc}$. Sediment losses were estimated on the basis of the ratio of areas of funnel opening relative to the gap around the funnel and the average cumulative sediment trapped during each phase. The area from which particles would collect in the gap was estimated as radius x length of the sediment trap flotation ring. Copepod biomass changes were estimated from average counts and carbon content determined from weekly net hauls.

3 Results

3.1 Chlorophyll a and the analysed phases of the experiment

The experiment can be divided into three phases of autotrophic bloom development. An increase in Chl a (Fig. 3) started in all mesocosms already during CO₂ manipulation and peaked on t7. A CO₂ effect on Chl a concentrations during phase I was not observed. After nutrient addition (t13), there was a lag phase of 2 to 3 days until Chl a started to increase. Phase I carbon budget-calculation starts on t8, just after the phase I peak, and is thus describing processes during the bloom decay until t15. During phase II, from t13 onwards, large parts of added inorganic nutrients were consumed and budgets for C, N and P were calculated for build-up and decay of the second bloom peak until t20. Here, the Chl a peak of the high CO₂ treatments was higher than the one at intermediate and low CO₂ levels. During phase III, starting on t20, Chl a at low and intermediate CO₂ started to increase exponentially, reaching maximum concentrations on t27 and declining thereafter. In contrast, at high pCO₂ Chl a increased more slowly, not reaching peak values until the end of the experiment.

Maximal Chl a concentrations of ~3 µg L⁻¹ during the course of the experiment are rather low considering the 5 µmol kg⁻¹ NO₃ and 0.32 µmol kg⁻¹ PO₄ added. Chl a concentrations were transformed into estimates of organic carbon for the autotrophic community using Chl a to carbon ratios by Li et al. (2010), with 0.02 g Chl a g C⁻¹ for a phytoplankton community with low contribution of diatoms. Transformation reveals that the contribution of photoautotrophic biomass (up to 15 µmol kg⁻¹ C) to the standing stock of particulate carbon, PC, (up to 40 µmol kg⁻¹) was rather low.

3.2 Carbon budget of the replicated control treatment

In Fig. 4 carbon pools of the untreated control mesocosms are plotted over the entire period of the experiment. The bloom development as displayed in Chl a (Fig. 3) is mirrored by build-up of ∆PC, while cumulative sedimentation of this biomass was rather low (Fig. 4a). Until t8, autotrophic uptake of inorganic carbon resulted in a simultaneous decrease of ∆CT, which was partly compensated by in-gassing of CO₂ from the atmosphere. Hereafter biomass decreased and PC was partly respired back into the CT pool, sedimenting out or being released as DOCcalc. Three days after the addition of inorganic nutrients (t16 up to t19), ∆PC build up combined with sedimentation was not leading to changes in ∆CT but was compensated by CO₂ entering the mesocosms from the atmosphere. During the first 19 days, the sum of particulate carbon produced in the control mesocosms roughly equaled the sum of inorganic carbon consumed, indicated by DOCcalc approaching zero during this period. Measured DOC values are included in Fig. 4b. Apparently, day-to-day variability in this dataset is much larger than the amount of carbon potentially available for the formation of DOC. This is evident from the sum of other measured carbon species shown as DOCcalc in Fig. 4a. Parallel variations of Pool X to DOC data (Figs. 2, 4b) identify measurement results to be unrealistic.

As shown in Fig. 4c, the temporal development of DOCcalc in the two control treatments was very similar. Variability of DOCcalc during most of the experimental time was relatively small (DOCcalc was on average -0.43 ± 2.7 µmol kg⁻¹ for
3.3 CO2 effects on carbon budgets

Changes in inorganic carbon concentrations between t8 and t27 (Fig. 5a) are correlated to CO2 levels with the highest CO2 treatment showing the strongest decrease in CT. At high pCO2 the decrease was rather linear over time, whereas there was only a minor change in CT concentrations in the low CO2 treatments during the first 12 days of this period. Most of these CO2-related differences were caused by gas exchange with the atmosphere. One third (24 µmol kg\(^{-1}\)) of the CT decrease at the highest CO2 over the whole
By separating the budget into three phases of the experiment, changes in elemental pools in the nine mesocosms can be directly compared using regression analyses. Because inorganic nutrients were low at the beginning of phase I, there was no apparent uptake and inorganic nutrient budgets were thus not calculated. However, ΔCT (Fig. 6a) showed a relatively strong decrease of inorganic carbon at high CO₂ compared to net heterotrophic production at low CO₂. This highly significant CO₂ effect on carbon uptake was not reflected in particulate carbon accumulation (Fig. 6b, Table 3). ΔPC was decreasing from the 18 bloom peak, while sedimentation was equally low in all treatments. This translates into a significant positive correlation of ΔDOCcalc to CO₂ in phase I (Table 3), causing an offset towards elevated ΔDOCcalc at high CO₂ that persisted over most of the experimental time (Fig. 5f).

3.5 Phase II

During phase II, dissolved inorganic matter (DIM) concentrations, comprising inorganic carbon (Fig. 6b) together with inorganic nutrients, decreased significantly stronger at high CO₂ (Table 3). Although statistical tests could not detect a significant CO₂-related increase in all pools of dissolved and particulate organic matter, significant positive trends in Chl a (Fig. 3), ΔPON, ΔDOP and ΔDOCcalc (Fig. 6b, Table 3) suggest a general positive effect of CO₂ on phytoplankton production during phase II. Mass balance indicates that surplus carbon taken up at high CO₂ accumulated in the dissolved organic pool (ΔDOCcalc), while nitrogen remained mainly in the particulate fraction and phosphorus was almost equally partitioned between both the particulate and dissolved organic pool (Table 3). The small sedimentation event peaking on t16 can be mainly allocated to Cirripedia larvae migrating into the sediment trap (Figs. 7a, 6g). The settling of these meroplanktonic larvae decreased metazooplankton biomass by 40-60% (from overall average 5.0 ± 1.8 to 3.1 ± 1.1 µmol kg⁻¹) over the course of the experiment, thereby contributing ~60% to the export flux during phases I and II (see also Niehoff et al., 2013). A sedimentation event caused by sticky nets of pteropods introduced into the mesocosm during phase I was not detected. The fairly large dead individuals were excluded from the sediment samples.

3.6 Phase III

In phase III, CO₂-related trends in dissolved inorganic matter uptake rates of phase II are reversed. Significantly more inorganic carbon was consumed at low CO₂ (Fig. 6i), resulting in significantly stronger build-up of PC (Fig. 6j) and export of this material (Fig. 6k). Trends in inorganic carbon uptake during phase III were parallel to trends in uptake of...
Table 3. Results of F tests (regression analyses) for CO₂ dependent changes in pool sizes of C, N and P during the three phases of the experiment. Analysed delta values for each phase are calculated using the first day of the respective phase as a reference point. Mean delta concentrations of the elements in particulate organic (POM), dissolved inorganic (DIM) and dissolved organic matter (DOM) as well as sediments (Sed.) and pools calculated by mass balance (DOC_{calc}, DON_{calc}, POP_{calc}) were plotted against mean CO₂ concentrations during the phase. Significant trends (p < 0.05) are marked grey. Direction (Dir) of trends are given for correlations p < 0.1. "Neg." stands for negative correlation to pCO₂ and would for example mark a significantly stronger decrease in dissolved inorganic matter (DIM) with increasing pCO₂, while "Pos." stands for positive correlation to pCO₂ and could therefore mark significantly increasing concentrations, for example, POM with increasing pCO₂.

3.7 Stoichiometry of particulate matter

Elemental ratios of water-column particulate matter were always close to Redfield ratios (Fig. 8). CO₂ or nutrient manipulation did not cause strong changes in elemental composition of particulate matter. C/N and N/P ratios of material sampled from the sediment traps were generally similar to ratios obtained for water-column particulate matter, with mean N/P ratios of the sediment slightly higher than respective values from the water column. During the last days (t27–t30) of the experiment, C/N ratios of water-column particulate matter increased in all mesocosms (Fig. 8a). This increase was significantly stronger for the low CO₂ treatments. The same general increase was observed in the sediment, but here C/N started to rise already on t24, reaching maximum values in the water column (Fig. 8b). Diatom aggregates contributed the largest fraction of the sediment during the last week of the experiment as documented by a strong increase in biogenic silica fluxes (Fig. 7b), an elevated Si/C ratio (Fig. 7c) and microscopic inspection.

4 Discussion

4.1 Phase I

In the control treatments, dynamics in total inorganic carbon and gas exchange over the first 19 days of the experiment are well represented by measured production, export and respiration of particulate organic matter (Fig. 4a). Thus,
the carbon budget was closed with $\text{DOC}_{\text{calc}}$ approaching zero at low $\text{CO}_2$. At high $\text{CO}_2$, however, there was significantly higher carbon consumption during phase I (Figs. 5c, 6a). Due to a strong vertical light gradient, $^{14}$C gross primary production measured at 1 m water depth was high, showing a clear, positive correlation to $\text{CO}_2$ (Engel et al., 2013). In contrast, oxygen based production estimates by Tanaka et al. (2013) incubated at 3 m water depth were low and seem to be already partly balanced by respiration. The extra carbon ($\sim 13 \mu\text{mol kg}^{-1}$) consumed at high $\text{CO}_2$ was not found in any of the particulate carbon pools (Fig. 6b, c), it was thus allocated to $\text{DOC}_{\text{calc}}$. Despite strong variability, statistical analyses of $\text{DOC}$ measurements as well as $^{14}$C $\text{DOC}$ primary production measurements by Engel et al. (2013) support our interpretation of increased $\text{DOC}$ production at high $\text{CO}_2$ in the phase before nutrient addition. $\text{DOC}$ production was probably related to phytoplankton exudation but also to viral lyses of nanoplanктон and microzooplankton grazing, both initiating the decline of the phase I bloom (Brussaard et al., 2013). Stronger microzooplankton grazing at low $\text{CO}_2$ during phase I was stated by de Kluijver et al. (2013) and Brussaard et al. (2013). Enhanced primary production at high $\text{CO}_2$ (Engel et al., 2013) presumably in combination with opposing strong heterotrophic loss processes at low $\text{CO}_2$ (Brussaard et al., 2013) were resulting in net uptake of inorganic carbon in the future $\text{CO}_2$ treatments and concomitant release of inorganic carbon in the low $\text{CO}_2$ controls (Fig. 6a). Rapid cycling of carbon during phase I obviously resulted in accumulation of $\text{DOC}$ at high $\text{CO}_2$ that was not readily bioavailable and persisted at least during phase II, in which net production of $\text{DOC}$ was considerably lower (Fig. 5f, see also Engel et al., 2013). A semi-labile nature of the produced dissolved organic matter in this experiment becomes also evident from apparent substrate limitation of heterotrophic bacteria during the entire experiment, detected by Piontek et al. (2013).

The phenomenon of inorganic carbon drawdown with low net consumption of N or P, called carbon over-consumption (Toggweiler, 1993), was enhanced at high $\text{CO}_2$ between t8 and t15. Such feature was already found in incubations of natural Atlantic plankton communities under high $\text{CO}_2$ (Schulz et al., 2008; Bellerby et al., 2008; Riebesell et al., 2007; Delille et al., 2005; Engel et al., 2004a; Egge et al., 2009; Hein and Sand-Jensen, 1997) and is also indicated by increased cumulative $^{14}$C primary production observed during the experiment by Engel et al. (2013). The final product
of enhanced photosynthetic activity could often not directly be measured, but was hypothesised to be released as DOC, subsequently occurring as TEP (Engel et al., 2004a). Sedimentation of aggregated DOC in the form of TEP was hypothesised to cause increased carbon loss under high CO₂ in the PEECE (Pelagic Ecosystem CO₂ Enrichment) III study (Schulz et al., 2008) and in further previous experiments (Engel et al., 2004b). In this experiment, an increased contribution of freshly fixed ¹³C to high CO₂ sediments during phase I was argued to be caused by sinking of TEP by de Kluijver et al. (2013). TEP formation implies a flux of DOC into the PC pool, but neither increased bulk sedimentation nor increased carbon contents of sediments or of water-column particulate matter under high CO₂ were measured. Sediment fluxes were low and indication for TEP as a relevant aggregation factor was not detected. Sugars serving as precursors for TEP were possibly produced at concentrations too low to form relevant amounts of aggregates or were consumed by the bacterial community right after release (Pio-

Fig. 7. Vertical fluxes for carbon (a) and biogenic silica (b) normalised to kg seawater and day. Biogenic silica to carbon ratios in the sedimented material are shown in (c). Treatment levels and vertical dashed lines are coded as described for Fig. 3.

During phase II the trends in uptake of inorganic C, N and P after nutrient addition were consistent with trends in Chl a. Elevated CO₂ concentrations seemed to have a stimulating effect on growth of the dominating picoeukaryotic primary producers (Brussaard et al., 2013; Schulz et al., 2013), leading to increased uptake of inorganic matter (Table 3, Fig. 6c), as well as increased cell numbers and Chl a. However, increasing biomass production as a result of enhanced nutrient uptake at high CO₂ during the bloom of picoeukaryotes in phase II was hardly detectable as particulate organic matter build-up and did not cause a significant sedimentation event (Figs. 6f, 5g). A peak in carbon export caused by Cirripedia larvae (116, Fig. 7a) shows that the settling of meroplankton can seasonally account for a large portion of vertical fluxes in coastal ecosystems. This finding is in agreement with ¹³C tracer data by de Kluijver et al. (2013). Generally low enrichment of sediment with the tracer during phases I and II can only be explained by high contents of zooplankton and "old" detrital material. Build-up of autotrophic biomass in the water column, estimated from Chl a as well as from biovolume of picoeukaryotes (Brussaard et al., 2013) can only account for the amount of inorganic C, N and P consumed during the first days of phase II. Thereafter, phytoplankton standing stocks were diminished and kept at a relatively low level by microzooplankton grazing and viral lyses of picoeukaryotes (Brussaard et al., 2013). Nutrient and carbon uptake continued during the time of strong biomass loss. Low C/N and C/P inorganic uptake ratios in all treatments suggest overall elevated production of organic P and N compared to organic C during phase II (Silyakova et al., 2012). Significant CO₂-correlated differences in ΔPC as well as ΔPOPcalc could not be detected during the entire phase II (Table 3). Dissolved organic matter is indeed showing positively CO₂-related differences in ΔDOCcalc (Fig. 6h) but also in ΔDOP. Release of cell contents rather than exudation may have been the source of this DOM at nutrient-replete conditions, as enhanced autotrophy at high CO₂ was strongly top–down controlled (Brussaard et al., 2013). In contrast to P and C, enhanced uptake of inorganic nitrogen at high CO₂ was also reflected in higher ΔN and only minor amounts of N accumulated in DONcalc. Nitrogen was obviously preferentially incorporated into the heterotrophic community compared to C and P (Table 3).
4.3 Phase III

A relatively diverse phytoplankton community comprised of picoeukaryotes, co-dominated by diatoms and dinoflagellates established during phase III (Schulz et al., 2013; Brusaard et al., 2013). Biomass build-up resulting from fast carbon and nutrient drawdown did not seem to be limited by strong heterotrophic loss processes as observed in the previous two phases. This bloom showed higher C, N and P uptake rates at low CO₂, whereas under high CO₂ uptake was already slowing down due to nutrient depletion after the phase II peak (Fig. 6i). Reduced growth at high CO₂ in phase III was reflected by significantly lower ΔPC, ΔPON, and ΔPOP (Table 3). Diatoms, contributing relatively low biomass to the pelagic community (Schulz et al., 2013), increasingly dominated the sediment material from the beginning of phase III in all treatments. In the sediment material, this is illustrated by increasing BSi/C ratios from t20 onwards (Fig. 7c), concurring with microscopic observations of large quantities of diatom chains and their fatty acid signature detected by de Kluijver et al. (2013). Overall, higher biomass build-up seemed to be causing a sedimentation event of diatoms, forming aggregates with other particles, transporting them into the sediment trap. In contrast to the previous two phases, ¹³C tracer concentrations indicate that there were even higher contributions of freshly fixed carbon to sediments than to water-column PC (de Kluijver et al., 2013). The retention food web, quickly recycling freshly produced biomass, seems to have shifted towards an export community in phase III (Wassmann, 1997). Strongly reduced export at high CO₂ was obviously due to nutrients being diminished by enhanced growth during phase II. Unfortunately, the total amount of export production cannot be calculated for this period, as measurements ended before peak sedimentation rates were reached (Fig. 7a). In addition to that, DOCcalc and wall-grown biomass, not being exported, were exponentially increasing (Fig. 4c). However, an export flux at high CO₂ comparable to fluxes observed at low CO₂ occurring after the end of our measurements (t30) seems unlikely, as inorganic N and P were depleted at t28. Until nutrient depletion, significantly less carbon uptake, PC and PON accumulation in the water column and less export of C, N and P were observed at high CO₂ during phase III.

4.4 Stoichiometry of exported particulate matter

Temporal trends in elemental composition of the sedimented particulate matter were very similar to that of the water column during most parts of the experiment (Fig. 8). Carbon isotope tracer data in sediments suggests that there was mostly an under-representation of phytoplankton biomass (de Kluijver et al., 2013). Elemental composition of sediment was overall similar to water column particulate matter. This classifies sinking material sampled at the bottom of the shallow mesocosms to be relativity fresh. Nevertheless, sinking detritus and digested material produced by the large heterotrophic community was probably responsible for the slight general offset in composition of sedimenting material towards higher C/N and N/P ratios throughout the experiment. While changes in particulate matter composition in response to future CO₂, reported from laboratory experiments on phytoplankton (Burkhardt et al., 1999; Burkhardt and Riebesell, 1997), are varying between species in strength and direction, differences in organic C/N/P ratios of primary producers growing under inorganic nutrient limitation and repletion are a common phenomenon (Klausmeier et al., 2004). The fact that we did not observe strong changes in response to nutrient or CO₂ addition, during this experiment is likely a
result of the diverse composition of POM, with phytoplankton comprising only a relatively small fraction during large parts of the experiment. Fast recycling of readily available N and P compounds during phase I were obviously covering the nutrient demand of phytoplankton (Schulz et al., 2013) and probably comprised a large part of the fluxes even during nutrient replete phases of the experiment.

The observed increase of C/N ratios in the sediment compared to the water-column particulate matter during phase III correlates with the occurrence of diatoms and increasing silicate flux (Fig. 7c). This diatom ballast or aggregation effect caused the over-representation of fresh carbon-rich particles in the sediments. The same C/N increase as in the sediment occurred later and less pronounced in the water column; here diatoms and fresh material are measured against a much larger background of other water-column particulate matter, thus diluting this signal.

On t20, higher C/N ratios at low CO₂ appeared in water-column particulate matter. Similar to the general increase of C/N in all mesocosms, also the CO₂ effect on C/N was amplified in the sediment. Mesocosms showing stronger elevated C/N ratios on the last day had also higher sedimentation rates of C, N, P and Si (Table 3). Carbon uptake beyond the day of nutrient depletion could not be determined, as the inorganic carbon dataset ends on t27. But already until t27 inorganic carbon to nutrient uptake was much higher at low CO₂ during phase III and thus even during the combined post nutrient phase (II + III) (Silyakova et al., 2012). A combination of high uptake rates and the shift towards increased C/N on the last days overcompensated initially higher uptake at high CO₂ during phase II. Elevated C or reduced N content of the phytoplankton community might have been due to growth limitation by dissolved inorganic nitrogen with concentrations below 1 µmol kg⁻¹ (Klausmeier et al., 2004) already since t24 in all treatments.

4.5 Synthesis

Despite all efforts in determining all relevant elemental pools of C, N and P in regular temporal intervals, budgets could not readily be closed. This was mainly because of unsatisfying precision in DOC, DON and POP as well as wall growth towards the end of the experiment. However, gaps in the budget could be narrowed down by introducing novel methodology to determine gas exchange and sedimentation. It could be demonstrated that measured pools in large mesocosms can be quantitatively evaluated against each other. Moreover, using mass balance, problematic measurement parameters as well as technical and operational problems could be identified and their relevance could be quantified. In later experiments, improved sediment traps, an improved DOC sampling strategy as well as regular cleaning of the walls solved the most prominent problems pointed out in this study (see improved methods in Riebesell et al., 2013). The particular reason for the lack in precision in DON and POP within this dataset could not be ascertained.

Future CO₂ concentrations were found to stimulate autotrophic production twice during the course of this experiment. First during phase I, when increased inorganic carbon uptake by nanoplankton at high CO₂ was directly channelled into dissolved organics. Secondly, during phase II, when enhanced growth of picoeukaryotes diminished inorganic nutrient concentrations at high CO₂, resulting in less organic matter being exported in phase III. During this experiment, both positive effects on primary producers had negative influence on carbon export.

After phase I, community composition and carbon flows had changed. Later effects were therefore a product of complex resource competition and cascading loss processes modified by CO₂ and preceding production. The dominating producers or consumers in a mesocosm had responded to the manipulation at the beginning of the experiment, the following effects were multi-causal. Growth enhancement of nanoplankton and picoeukaryotes during phase I and II (Brussaard et al., 2013; Engel et al., 2013; de Kluijver et al., 2013) might have caused most of the CO₂ effects on bloom dynamics observed during and after their occurrence. Therefore, e.g. direct physiological CO₂ effects on plankton dominating within phase III would be a matter of speculation due to the different nutrient situation already in the beginning of phase III. This demonstrates that ecological data are of substantial importance in making biogeochemical response patterns comparable between experiments. Apparently, responses found for the retention type community, which was present at the start of this experiment, are not directly comparable to earlier findings for export systems such as the coccolithophore blooms in Norwegian coastal waters compiled by Riebesell et al. (2008). Community experiments always have to be seen as case studies with results primarily valid for the specific community composition enclosed at the start of the experiment. Further experiments will show whether CO₂ enhanced DOC production and growth of smaller phytoplankton can be consistently found at similar community composition.

Laboratory studies performed on single species are ideal to detect physiological CO₂ effects, whereas the importance of these effects within a natural ecosystem is always difficult to extrapolate (Riebesell and Tortell, 2011). In this experiment, ocean acidification/carbonation affected small phytoplankton, which in turn significantly influenced principle ecosystem functioning. Whereas enhanced growth of picoeukaryotes itself had no immediate effect on carbon export fluxes, their footprint in the nutrient budget controlled export fluxes later during the experiment. Identifying species that have the potential to change biogeochemical fluxes by influencing community succession is an important task for future mesocosm experiments. Focussing from the community to the species level instead of extrapolating from the laboratory
to the field could accelerate the progress of finding general biogeochemical response patterns.

Acknowledgements. This work is a contribution to the “European Project on Ocean Acidification” (EPOCA) which received funding from the European Community’s Seventh Framework Programme (FP7/2007-2013) under grant agreement no. 211384. Financial support was provided through Transnational Access funds by the European Union Seventh Framework Program (FP7/2007-2013) under grant agreement no. 22822 MESOAQUA and by Federal Ministry of Education and Research (BMBF, FKZ 03F0608) through the BIOACID (Biological Impacts of Ocean ACIDification) project. We gratefully acknowledge the logistical support of Greenpeace International for its assistance with the transport of the mesocosm facility from Kiel to Ny-Ålesund and back to Kiel. We also thank the captains and crews of M/V ESPERANZA of Greenpeace and R/V Viking Explorer of the University Centre in Svalbard (UNIS) for assistance during mesocosm transport and during deployment and recovery in Kongsfjorden. We thank the staff of the French–German Arctic Research Base at Ny-Ålesund, in particular Marcus Schumacher, for on-site logistical support.

3. Technical and methodical improvements

Analysing the Svalbard elemental dataset revealed some weaknesses of the set-up. DOC was not measured at a satisfying precision and had therefore to be excluded from elemental budgeting. This lack of precision could be solved by switching to an acid washed sampling container in the following experiment. However, dissolved organic carbon, nitrogen and phosphorus remain the most problematic parameters also in later experiments. High background concentrations, easy contamination and the multitude of processing steps during analyses make it hard to meet precision standards of most of the other analyses. Further delicate issues like wall growth, dead volume below the sediment traps associated with potentially lost sediments as well as comparatively sparse data on zooplankton elemental composition had to be evaluated carefully. Yet, most of those drawbacks could be removed for the next experiment.

3.1 Cleaning the walls

Beside variability in DOM measurements, wall growth was another critical point when constructing the elemental budget for the Svalbard 2010 experiment. The idea of a cleaning ring was born on Svalbard, when apparent wall growth had to be quantified in order to close an elemental budget at the end of the study. On site, it was constructed from one of the mesocosms sediment trap floatation rings. Despite initial handling problems of the large heavy weighted ring, first cleaning results were rather convincing. Continuous improvements on the rope system, a closing and opening mechanism, the circumferential silicon wiper and an electric winch, made regular inside-cleaning of the bag efficient and practicable. “Easy cleaning” is important in any study as wall growth was proven not to be confined to eutrophic environments. Later studies showed benthic cyanobacteria to be competitive at inorganic nutrients on nanomolar levels. In spite of our success in keeping benthic biomass insignificant compared to plankton biomass by regular cleaning, the presence of a large surface area remains an issue when comparing mesocosm community composition to open water plankton. Providing settling ground, even only for a short duration, favours the development of benthic biofilms and microalgae. Benthic species may become enriched in the mesocosm compared to open waters over time. A clear advantage of the KOSMOS mesocosms is the low relative surface area of ~2m²/m³ compared to smaller set-ups. The cylindrical part of the mesocosm, rigid due to 200 kg heavy bottom weight and 500 µm foil, can be automatically cleaned, whereas cleaning of more light weighted constructions commonly used for mesocosm bags would be not feasible.
Improvements

Efforts to reduce biofouling on the mesocosm surfaces and to improve durability of the system enables us for the first time to conduct long-term mesocosm studies in more relevant areas exposed to moderate marine weather conditions.

Long-term mesocosm studies will have the potential to firstly increase relevance of the datasets by including effects on higher, economically more important trophic levels; and secondly enhance significance of the findings through improved coverage of secondary and long-term treatment effects. With experiments lasting for several months, mechanisms relevant on a seasonal scale can be addressed. The most important cleaning tools are shown in Fig. 3.1.

Figure 3.1. a) Weighted cleaning ring with silicon wipers used to prevent biofouling on the inside walls of the mesocosm. Ring can be opened for easier deployment (detail). b) Professional diving scrubber for cleaning of outer fouling. (Drawings by Detlef Hoffmann)

3.2 Sediment traps

Since the first large scale KOSMOS trials in 2007, funnel shaped sediment traps with vacuum sampling tube to the surface were installed in the bottom of the mesocosm. Due to strong variation of daily sampled sediment amounts within the first trials, sediment traps were enlarged for the 2010 study to cover the entire bottom surface of the mesocosm. The large trap should
collect all material settling and thereby account for possibly uneven distribution of sinking material among the bottom area as well as avoid trapping of resuspended material. The quantitative extraction of freshly settled material from the system eliminates the input of remineralised nutrients from below. This is a basic prerequisite for elemental budget calculations, as sediment traps on sub-units of the surface can only provide information on composition of settling material that was trapped and not on the composition of bulk exported material that underlies further degradation remaining within the system.

The large floating sediment trap as used in Svalbard 2010 was relatively quickly installed in response to inconvenient results from smaller sediment traps in a 2009 trial. However, this construction involved some disadvantages as discussed in Publications 2.1 and 2.3. The limited exchange of water with the space below the trap as well as possible losses of sediment into this space led to a principally new design of the bottom construction. The custom shaped fibreglass flanges attached and closed by divers have been successfully proven and tested in five deployments since 2010. Close to neutral in buoyancy funnel flanges are easy to handle by scuba divers and can be fitted with a multitude of different sealing gaskets.

3.3 Gas exchange estimates

Gas exchange estimates as described in Publication 2.3 were further developed to provide diapycnal fluxes of dissolved substances in stratified mesocosms, beside estimates for air-sea gas exchange. In later studies, depending on mixing regime in the mesocosms, integrated deep- and surface mixed layer as well as discrete surface (1 m) tracer samples were taken additionally to the total depth-integrated samples. Air-sea fluxes detected as changes in the N₂O inventory can thus be related to air-sea gradients as well as diapycnal gradients within a simplified stratification model. Biological influence on surface water CO₂ fluxes can be important in stratified mesocosms, especially during periods of high primary production. To improve CO₂ gas exchange estimates, the depth-integrated carbonate chemistry dataset was accomplished by routine surface (1 m) pCO₂ measurements using a HydroCTM CO₂ sensor (Contros Systems and Solutions GmbH). Uncertainties arising from estimated chemical enhancement of CO₂ air-sea gas exchange were narrowed down by continuous measurement of sea surface (10 cm) temperature within the mesocosms using HOBO precision temperature loggers.

3.4 Sampling the upper trophic levels

Many questions concerning ecological and biogeochemical responses of organisms in the size range from bacteria to metazooplankton can be answered using smaller and thus much cheaper
Improvements

 experimental setups. Mesocosms larger than 50 m³, however, offer the unique opportunity to study large organisms that need considerable amounts of space and resources for their natural development within an enclosed ecosystem. Experiments on economically or biogeochemically highly relevant food web components such as fish, jellyfish, appendicularians or pteropods usually suffer limitations arising from external or artificial food supply. Within the KOSMOS mesocosms, we were able to observe the natural occurrence of fish developed from eggs enclosed in the beginning of the experiment, as well as the establishment of pteropod, jellyfish and appendicularian populations. Datasets on the abundance of those species occurring in relatively low concentrations of only several specimens per m³ were often limited due to problems of adequate sampling. Despite large efforts in the end of the experiment, juvenile fishes observed in the Svalbard 2010 and the Bergen 2011 study could not be caught in sufficient numbers to produce statistically valid data. An appendicularian bloom, obviously responsible for the vertical transport of large amounts of gelatinous material in Bergen 2011, could not be sufficiently documented in terms of animal abundance to draw conclusions on apparent treatment effects.

Two strategies were developed to overcome these sampling limitations. Firstly, a fishing net that allows retrieving all animals from the mesocosm after an experiment is terminated, regardless of escape capabilities. Connected to the cleaning ring, the constructed net covers the full diameter of the mesocosm. It is brought to the bottom of the enclosure in a folded configuration. By putting strain on a net control line, the funnel shaped net unfolds and can be pulled slowly through the mesocosm, sealing with the walls on all sides (Fig. 3.2). In the Kristineberg 2013 long-term study, more than 500 juvenile herrings of around 5 cm length could be retrieved. The animals hatched within the mesocosms and grew much faster in the mesocosms compared to their brothers and sisters fed with natural plankton in a parallel lab experiment. Soon after hatching, larvae disappeared from weekly zooplankton samples, as they grew fast enough to escape the 20 cm net opening used during routine sampling.
Figure 3.2. The mesocosm fishing net. a) Open configuration - both halves of the net ring on one side, so that cleaning ring can be opened enabling installation. During lowering, both halves of the net ring are hanging vertically to allow passage of the net below enclosed animals (net not shown). b) Net control line is pulled when the construction reached the bottom of the mesocosm - the net unfolds to cover the entire mesocosm surface and seals with the walls (net not shown). c) The unfolded net - can be slowly pulled up using the net control line. Reverse procedure for deinstalling and retrieving the sample. (Drawings by Detlef Hoffmann)

The second technical development gives timeline data on the development of large rare species. Frequent sampling of animals, present in low numbers of only a few hundred per mesocosm, would diminish the population and potentially lead to extinction of the animals from the mesocosm. Coordinated by fellow scientist Jan Büdenbender, a camera system was developed in cooperation with the company Develogic Subsea systems. Named “KielVision”, this camera is designed to quantitatively screen a water column of 1.2 m³ within the mesocosm for larger particles (Fig. 3.3). Lowered slowly down the mesocosm, KielVision is taking high resolution pictures of defined water slices every 2 cm. Based on these pictures, objects larger than \(\sim 200 \mu m\) can be non-destructively quantified and measured using the software package ZooImage (http://www.sciviews.org/zooimage/). KielVision is designed to not only create high temporal resolution abundance and growth estimates for the upper trophic levels, but also bring light into mechanisms causing sedimentation events. Observation of water column aggregation should help
Improvements

Connecting events of strong sediment flux to physical, biological and chemical circumstances described in the mesocosm.

Figure 3.3. KielVision. When lowered through the mesocosm, a defined water volume within the bottom frame is illuminated by red light flashes. The camera installed in the glass dome takes high resolution pictures at a frequency of up to 18 per second. An inbuilt computer connects pictures to pressure data and prepares files for later analyses. Lowered once through a 20 m mesocosm, a vertical particle profile capturing particles from 1.2 m³ of water is recorded. Plankton organisms larger than 200 µm can be identified from automatically sorted libraries. (Drawing by Devologic)
4. Perspectives

In the following paragraphs, biogeochemical questions and hypotheses for past and future mesocosm experiments are discussed. New technical approaches to tackle those questions in the future are presented.

All past KOSMOS experiments investigated the effect of increased CO$_2$ concentrations on temperate to Arctic marine ecosystems. Marine regions, plankton communities and seasons varied between the experiments, leading to different CO$_2$ responses of the enclosed plankton communities. To move from case studies towards more general answers, improvements in experimental set-ups, sampling protocols and data analyses are needed. Specific findings of experiments performed since 2010 are not discussed within this thesis, but some general observations are used to formulate a new hypothesis for future ocean acidification experiments.

Possible application of KOSMOS mesocosms for unravelling biogeochemical fluxes connected to sporadic nutrient inputs in oligotrophic oceans (e.g. eddy pumping, hurricane blooms, artificial upwelling, dust / volcanic ash events) are proposed. Funding for this important basic research may be raised with reference to risk-benefit assessment for potentially socio-economically important artificial upwelling strategies.

4.1 Optimising data acquisition and analyses

Biogeochemical results from laboratory experiments with single species and on short time scales were used to formulate most hypotheses for our community experiments. Major questions of our experiments concerning the effect of increased CO$_2$ levels on microbial biogeochemistry are:

- Are detrimental effects of seawater acidity on coccolithophore calcification significantly affecting future carbon export due to reduced carbonate ballast?
- Is future increased CO$_2$ availability leading to carbon overconsumption by phytoplankton? Will future particles thus be enriched in carbon?
- Is carbon export increased due to the formation of TEP from exuded overconsumption?
- Are CO$_2$ effects on cyanobacteria changing the oceans nitrogen budget?

We were the first describing all relevant parts of the system within large scale mesocosm experiments. Recorded data describe pools and fluxes of the most relevant bioactive elements as well as community composition at high temporal resolution. In general the enclosed ecosystems appeared surprisingly robust, often showing ecological and biogeochemical patterns comparable
between mesocosms and the surrounding waters for weeks and months. However, most of the
questions addressed over the past years cannot yet be readily answered. We are so far unable to
answer those questions with a simple yes or no, even though plenty of data on the enclosed
system were collected and various CO₂ effects have been detected. The achieved data are very
complex and uncertainties as to the universal applicability of the findings remain. On the
ecosystem level, diverse species assemblages may often level out effects, while strong control
mechanisms such as nutrient availability and grazing pressure may enhance or override CO₂
effects of single species physiology. While a coccolithophore dominated species assemblage
may react to CO₂ as can be expected from monoculture experiments, coccolithophores that first
have to establish their dominance in a top down controlled community may appear more CO₂
sensitive. Elemental composition of particulate matter can be stable when species composition is
complex but may show large plasticity when the system becomes dominated by one blooming
phytoplankton group under similar experimental conditions. Organic exudates may accumulate
as DOC, aggregate as TEP or be immediately consumed by bacteria, depending on community
composition.

Compared to field data, mesocosm experiments have a temporal component that allows for
quantitative observation of the processing of matter within a system. However, the enclosed
community sampled at one point in time can only show us a snapshot of what may happen in the
given environment. Projections concerning the effect of CO₂ on biogeochemical fluxes in the
future can only be made by taking into account general ecological and physiological patterns
derived from as many community and single species experiments as possible. Meta-analyses of
the performed experiments are necessary to reveal general patterns. Inverse modelling enables
estimating carbon and nutrient fluxes between functional groups of the plankton community as
well as export and accumulation of dissolved organics (Vadstein et al., 2012; Vallino, 2000). As
shown in Fig. 4.1a, observations of standing stocks and rates from the experiment can be
accomplished using mass balance. Models can then be tested on further mesocosm datasets
featuring e.g. different starting composition of the enclosed community (Parsons, 1990). The
diversity in biogeochemical ecosystem models is high (Friedrichs et al., 2007; Arhonditsis and
Brett, 2004). Compiling an ecosystem model adapted to the specific observational structure and
scientific questions in KOSMOS mesocosm research is the critical step. Most global models
apply very simplified representations of the marine ecosystem (Fasham et al., 1990; Bopp et al.,
2013) which cannot capture community changes as observed in mesocosm experiments. More
complex models, describing functional types within phytoplankton, zooplankton and bacteria, as
well as their specific interactions are needed (e.g. Moore et al., 2001; Quere et al., 2005).
However, it has been debated if it makes sense to increase complexity of models in consideration of current gaps in parameter constraints through lack of data, and little knowledge about modelled ecological interactions (Flynn, 2005). On a global scale, simple models usually outperform complex approaches that are better fitted to regional ecosystems (Anderson, 2005). Mesocosms are the smallest scale an ecosystem model can be applied to. Results as the one presented in this thesis seem to be ideal to test model outputs while it is realistic to actually measure, directly during the experiment, rates and quantities needed to run a complex model.

Figure 4.1. Two different model flow networks used for biogeochemical mesocosm ecosystem modelling. a) The model by Schartau et al. (2007) includes carbon fluxes from inorganic carbonate system to sedimentation at relatively low ecological resolution with heterotrophs and autotrophs grouped. Aggregate formation mechanisms and DOM cycling are explicitly parameterised. b) The model by Vadstein et al. (2012) resolves community composition by three functional groups of autotrophs and four groups of heterotrophs. Most metabolic rates for the specific groups are adopted from the literature while some are measured. Sedimentation is represented via a one-way flow from autotrophs via heterotrophs and detritus including a microbial loop via dissolved organics. Inorganic carbon and export mechanisms are not explicitly parameterised. Abbreviations: DIC-dissolved inorganic carbon, TA-total alkalinity, DOC-dissolved organic carbon, TEPC-transparent exopolymer carbon, PCHO-polysaccharides, DIN / DIP- dissolved inorganic nitrogen / phosphorus, DON / DOP-dissolved organic nitrogen / phosphorus, DeN / DeP / DeC-detritus nitrogen / phosphorus / carbon, SeN / SeP / SeC-sediment nitrogen / phosphorus / carbon, COP-copepods, CIL-ciliates, BAC-bacteria.
Fractionation of particulate matter into size classes best fitted to represent parameterized functional groups should be elaborated. Rates of nutrient uptake, carbon acquisition, respiration, growth or grazing of exactly those groups, as well as their potential CO₂ dependence, should be determined. Measuring temperature dependence of key processes, effects of global warming could be investigated once the system is mathematically described. It would be useful to agree on a standardised protocol of data acquisition for all future experiments in close cooperation with modellers. In this cooperation of modellers and analysts, sensibilities of the model and capabilities of analytics can be aligned. Units of measurement output are currently often not quantitatively comparable. Specific rates measured in side-experiments are often not representative for the whole mesocosm (Engel et al., 2013). Measurements directly within the mesocosm deliver bulk estimates on larger timescales, but are quantitatively more robust (Czerny et al., 2013; Silyakova et al., 2013). Recalibration of multiple approaches to determine elemental flow pathways and rates should be applied. Net community inorganic carbon uptake based on presented gas exchange measurements and dissolved inorganic carbon could be accomplished by daily estimated rates derived from oxygen and CO₂ logger data. Turnover rates of carbon and nutrients within functional plankton groups can be estimated by addition of stable isotope tracers at certain periods within the experiment and their detection within specific fatty acids (Van den Meersche et al., 2004). Tracing pathways of ¹³C (de Kluijver et al., 2013) and ¹⁵N₂ (unpublished results) primarily fixed within the system was already practiced in KOSMOS mesocosms. The addition of labelled organic carbon, nitrogen or phosphorus could shed light into turnover times of dissolved organics and the activity of the microbial loop (Ducklow et al., 1986). Given the multitude of experimental approaches for unravelling the functions of enclosed ecosystems, numerical analyses of mesocosm data would help to improve concepts to constrain mechanisms for further experiments. Unprecedented interdisciplinary expertise is collaborating to describe ecosystem biogeochemistry in KOSMOS experiments. A complex picture of the ecosystem could be drawn with large gain for biogeochemical modelling with little additional efforts. Sensitivity of biogeochemical fluxes to unavoidable variability in physical forcing, enclosure size or initial composition of the community may be tested. Not only educated estimates for so called “mesocosm artefacts” can be generated; models can also provide a calculation basis for planning ecological manipulations e.g. the addition of larval fish.
4.2 Experiments on simulated eddy upwelling

Experimental plans focussing on CO₂ dependent mechanisms for particle export during tropical upwelling events will be presented. As mesocosm datasets become relevant for biogeochemistry only when describe natural events connected to relevant fluxes of matter, oligotrophic regions do not intuitively appear to be attractive research areas. Export events, by definition, can only be connected to new production and not to regenerated production when matter is recycled within the surface layer (Peterson, 1979). Seasonal thermal convection is one way nutrients can be supplied to the surface layer. Eckman transport resulting from a combination of wind and currents, modified by the Earth’s rotation, is another way responsible for a multitude of convectional patterns inducing upwelling of nutrient rich deep water (Marshall and Schott, 1999). Frequent nutrient inputs to the surface layer are predominantly found at high latitudes and on the eastern margins of the Atlantic and Pacific Ocean (Levitus et al., 1993). However, sporadical upwelling can also occur within generally oligotrophic subtropical and tropical regions. “Island mass effects” create blooms and nutrient rich eddies downstream of seamounts and islands (Gilmartin and Revelante, 1974). Upwelling often occurs at hydrographical fronts and predominantly along the intertropical convergence zone, where southern and northern hemisphere weather and current systems meet. Mesoscale eddies with lifetimes usually less than three weeks and in the size range of hundreds of km² carry nutrient rich waters deep into oligotrophic regions (Fu et al., 2010). Important sub-mesoscale turbulence patterns with low altitude profile are commonly not detected (Levy et al., 2001). Not only horizontal propagation of productive islands through oligotrophic waters is frequent, but also multiple mechanisms for vertical nutrient upwelling in those turbulent structures exist (Siegel et al., 2011). Geochemical tracer data suggest deepwater N inputs to most oligotrophic regions such as the North Atlantic subtropical gyre, large enough to support export of 3 molCm⁻²yr⁻¹ (Jenkins, 1988). The C/N ratio of the flux is assumed to be 6.5 according to Redfield. 3 molCm⁻²yr⁻¹ of new production is an extraordinary high estimate for ocean deserts such as the subtropical gyre. Observations and models propose not more than half of this flux for the subtropical gyres (Oschlies, 2008). Allowing for variable and often much higher C/N ratios (~10.2) observed in trapped material would cumulate discrepancies regarding the relevance of oligotrophic oceans for global carbon fluxes (Fig. 4.2; Tamelander et al., 2013). Such discrepancies in N input and C/N ratios are relevant to global carbon flux projections, especially in respect of the vast area covered by oligotrophic regions. However, mechanisms responsible for observed variability are largely unknown.
C/N variability of exported biomass during production events within oceanic deserts is virtually uncharacterised. Mesocosm experiments could provide first data on ecosystem biogeochemistry and CO₂ dependent export stoichiometry within such events.

Currently, modelled enhancement of biological production by mesoscale eddies varies between 20% and 100-200%, the latter values being probably overestimates (reviewed by Oschlies, 2008). Persisting discrepancies to geochemical estimates of new production may be partly explained by sub-mesoscale events not accounted for by eddy resolving models. Furthermore, wind induced mixing of the surface layer by tropical cyclones was observed to cause phytoplankton blooms of large spatial extension (Shi and Wang, 2007). Based on long-term satellite observations of the subtropical North Atlantic, it was hypothesised that cyclone events could contribute as much nutrients to surface layer production as estimated for mesoscale eddies (Babin et al., 2004). Permanently stratified ocean regions are expected to expand as a consequence of global warming. An observed decrease in satellite-derived ocean productivity within the last decade is mainly driven by changes in those oligotrophic areas, already representing 75% of the ice free global ocean (Behrenfeld et al., 2006). The important control of global ocean productivity by the El Niño-Southern Oscillation (ENSO) is also likely to be influenced by global warming. However, direction or magnitude of future changes in ENSO is not yet predictable (Collins et al., 2010).

Currently, modelled enhancement of biological production by mesoscale eddies varies between 20% and 100-200%, the latter values being probably overestimates (reviewed by Oschlies, 2008). Persisting discrepancies to geochemical estimates of new production may be partly explained by sub-mesoscale events not accounted for by eddy resolving models. Furthermore, wind induced mixing of the surface layer by tropical cyclones was observed to cause phytoplankton blooms of large spatial extension (Shi and Wang, 2007). Based on long-term satellite observations of the subtropical North Atlantic, it was hypothesised that cyclone events could contribute as much nutrients to surface layer production as estimated for mesoscale eddies (Babin et al., 2004). Permanently stratified ocean regions are expected to expand as a consequence of global warming. An observed decrease in satellite-derived ocean productivity within the last decade is mainly driven by changes in those oligotrophic areas, already representing 75% of the ice free global ocean (Behrenfeld et al., 2006). The important control of global ocean productivity by the El Niño-Southern Oscillation (ENSO) is also likely to be influenced by global warming. However, direction or magnitude of future changes in ENSO is not yet predictable (Collins et al., 2010).
From a technical point of view, artificial upwelling seems to provide nearly ideal prerequisites to perform meaningful experiments:

Plankton succession in response to sporadic upwelling events is poorly described compared to temperate regions and permanent upwelling regions. Data describing the North Atlantic spring bloom or the Peruvian upwelling system can be achieved by scheduled field campaigns. In contrast, plankton succession from nutrient input up to depletion and export within eddies can hardly be planned. Natural eddies can be well detected through sea surface height or Chl \(a\) measurements by satellites. But whenever water samples are taken, the system is already matured. Biogeochemical budgets are hard to construct due to on-going mixing processes.

Artificial upwelling events can be planned at any time of the year. Using deliberate deepwater upwelling into a closed mesocosm system, the initial ecosystem can be characterised before a precisely known amount of analytically characterised deepwater is added. Climatic conditions within the tropics are fairly predictable compared to e.g. the climatic situation at the onset of the North Atlantic spring bloom. The spring bloom is highly weather-depending, as it is initiated by favourable light and temperature conditions. Not only the timing of the bloom can vary by months, also the food web structure depends on temperature development and light.

Besides reproducible physical forcing, oligotrophic surface water as well as aged deepwater can be expected to have a rather constant and predictable biology (Cushing, 1989). Thus, reproducibility of deliberate upwelling experiments is further enhanced by food web structure in oligotrophic compared to eutrophic systems. Grazers specialised on large particles like diatoms, usually present at variable abundance within eutrophic or mesotrophic systems, are virtually absent in oligotrophic systems. A bloom of large phytoplankton occurring after nutrient input would be most likely bottom-up controlled and therefore characterised by freshly exported biomass at presumably variable C/N. The natural absence of benthic species in oceanic plankton would likely reduce effort and bias connected to wall grown biomass.

Other in eutrophic waters, surface water gas concentrations in oligotrophic regions are usually in equilibrium with the atmosphere. By deepwater addition, CO\(_2\) treatment levels adjusted according to IPCC scenarios are boosted towards stronger acidification by the naturally high CO\(_2\) concentrations in deep waters.

### 4.3 Potential CO\(_2\) effects on sporadic export production in oligotrophic waters

As a general pattern from our mesocosm experiments, we observed species composition to be the first and most sensitive parameter to react to any perturbation within a community. The pico- and nano-phytoplankton nearly immediately reacted with increased growth to elevated CO\(_2\) in almost
every experiment. Not always, however, with detectable consequences for biogeochemical fluxes. In the Svalbard experiment, nutrient uptake by picoautotrophs seemed to be affecting growth of diatoms following in the phytoplankton succession. Decreased nitrate availability within the high CO\textsubscript{2} treatments resulted in reduced carbon export compared to relatively nutrient replete low CO\textsubscript{2} treatments. Small-celled phytoplankton production at high CO\textsubscript{2} accumulated carbon within the dissolved organic fraction. This scenario featuring a picoplankton dominated surface water community confronted with a sudden nutrient input is the standard case for tropical upwelling events. Initially devoid of large diatoms, a CO\textsubscript{2} affected picoplankton community determines the growth conditions for blooming diatoms emerging after a lag phase. Also devoid of species grazing on microplankton, this community can be expected to export a large fraction of the freshly produced biomass. In earlier KOSMOS experiments, elemental composition of particles within complex species assemblages, co-dominated by several phytoplankton and zooplankton groups, was remarkably constant and close to Redfield. This was also the case in Svalbard during nearly the entire experimental duration, except of the last days when a blooming diatom-dinoflagellate assemblage became dominant. The high carbon content of those bloomers was presumably a result of nutrient limitation. With increasing sinking flux of fresh biomass, increasing carbon content in the sinking material was measured. As the ratio between picoplankton and blooming microplankton was CO\textsubscript{2} dependent, we could expect more fresh biomass to be exported at low CO\textsubscript{2}. Community shifts similar to those in tropical upwelling events, featuring a transition from diverse picoplankton assemblages to blooming microplankton, are connected to airborne dust or volcanic ash input into HNLC (High Nutrients Low Chlorophyll) regions (Olgun et al., 2011; Hamme et al., 2010).

Picoplankton is grazed and most efficiently packed into fast sinking faecal pellets by salps, appendicularians and thecosome pteropods within subtropical regions. Since the large size ratio of those microphages is at least 3.5 orders of magnitude larger than their pray, carbon turnover time is affected most efficiently. Small particulate, usually short lived, organic carbon is directly passed high up the food chain or down into deepwater layers (Fortier et al., 1994; Berline et al., 2011). Within two KOSMOS experiments of the recent years, we observed appendicularian blooms to develop fast and cause significant vertical fluxes by conglomeration of particles around discarded gelatinous houses. Abundance of fast reproducing pelagic tunicates is likely to be affected by CO\textsubscript{2} fertilised growth of picoplankton. By grazing also on free living bacteria, microphages could represent a link from dissolved organic carbon to export and high trophic levels (Urban et al., 1992), but could also promote the conservation of DOM when bacteria are top-down controlled. This potentially exceptional importance of microphages for
biogeochemical cycles in natural food webs is virtually unexplored. Strong direct detrimental effects of increased seawater acidity on pteropods, another important subtropical food chain component, were already documented in a previous KOSMOS experiment (Büdenbender et al., in prep.). Similar to pteropods, development and food chain effects in appendicularians can only be realistically investigated using large mesocosms.

A solution to the conundrum of high nutrient input in subtropical gyres (Jenkins, 1988), currently not supported by observations and models of biological production (Oschlies, 2008), may be found by better understanding of biogeochemical dynamics during upwelling events.

4.4 Experimental set-up for simulated upwelling events in mesocosms off Gran Canary Island

The mesocosms are deployed within oligotrophic waters and left covered by a 3mm net on the upper and lower end to allow water exchange with the surrounding for several days. Thus flushed from eventual contaminations, the mesocosms are closed and volumes are measured using a purified salt solution. The enclosed ecosystem can now be characterised and treated to reach desired CO₂ concentrations. After documentation of the treatment effects on the oligotrophic ecosystem, a depth-integrated volume of 8-16m³ can be removed using a diving pump (Grundfoss SP17-5R) moving continuously up and down the mesocosm. Removal of water is necessary to create space for consequent deepwater addition.

![Figure 4.3. a) Expander for compensation of ship movement. b) Deep-sea floatation and autonomous filling mechanism. c) 80m³ flexible tank welded from fibre reinforced food grade PVC. d) Weight system with acoustic release unit. Drawing: M. Deckelnick](image)

The water volume transferred is measured and dosed exactly using a ball valve in combination with an electromagnetic flowmeter (Endress+Hauser Promag P50). Before addition, the deepwater needs to be biologically and chemically characterised for the full set of parameters also sampled inside the mesocosms. Using the same pump as used for water removal, deepwater can be transferred from the floating 80 m³ reservoir tank to the mesocosms.
Deepwater can be sampled using two different strategies. The custom designed pump facility, used for injecting the deepwater, can also be used in combination with a CTD rosette to sample specific water layers of up to 400 m depth. The floating 80 m³ reservoir tank can either be filled using this pump or directly be lowered as deep as 900 m, where it is filled by an autonomous filling device (Fig. 4.3). The direct filling at depth is less time-consuming, but allows only water sampling from one predefined depth and not sensor operated sampling as compared to the pump. One of the two filling strategies can be chosen according to hydrographical conditions on site. The floating reservoir tank can be tugged to the mesocosm mooring site (Fig. 4.4).

Figure 4.4. a) Deep water sampling by filling the bag at up to 900 m depth. b) Deepwater sampling using the deepwater pump connected to a CTD rosette. c) Tugging of the bag to the mesocosm mooring site. One sampling procedure is sufficient to replace 15% of the mesocosm volume with deepwater. Depending on sampling depth, nitrate concentrations of up to 3 µmol/kg could be reached in each mesocosm. Nitrate depth distribution data are from the Canary Island Time Series ESTOC. Figure modified from a poster by O. Linas and M. Gonzalez-Davila, ESTOC (2012).

4.5 Mesocosms experiment for risk and benefit assessment of artificial upwelling strategies

Beside the basic scientific rationale for investigating ecological and biogeochemical processes connected to natural upwelling events, artificial upwelling is currently attracting commercial interests. Geo-engineering approaches targeted to sequester biologically fixed carbon in the oligotrophic open ocean were proposed for mitigate rising atmospheric CO₂ concentrations. The deployment of wave driven deepwater pipes to trigger phytoplankton blooms was proposed (Lovelock and Rapley, 2007; Karl et al., 2008) and prototypes have been tested. By vertical transport of CO₂ as well as of nutrients, upwelling is often rather a source than a sink for
atmospheric CO₂. Biogeochemical modelling suggests carbon sequestration into deep ocean waters to be negligible when Redfield composition C/N/P of upwelled nutrients as well as exported biomass is assumed (Oschlies et al., 2010). Side-effects of such an approach, in turn, may be severe. Fortunately, a ocean-wide installation of wave pipes (e.g. 1 km²; Oschlies et al., 2010) appears impossible from a technical as well as from an economical perspective. Still, artificial upwelling is well feasible and seems to offer multiple options for economic benefit on a more regional basis. Deepwater nutrients can be used to fertilise the oceans as a food source and temperature gradients to the surface water can be used to generate energy and freshwater. Technical concepts on the way to realisation include:

- air-conditioning using deepwater cooling
- ocean fertilisation to increase fishery yield (Kirke, 2003)
- large scale mariculture to cover the rising seafood demand
- production of electric energy or liquid hydrogen and deionised water using OTEC (Ocean Thermal Energy Conversion) (Nihous and Vega, 1993)
- soil cooling for production of temperate crops in the tropical regions using cold agriculture techniques
- ...

Technical realisations mostly combining several of the above listed technologies are illustrated in Fig. 4.5.

![Figure 4.5. a) Schematic representation of the ocean nutrient enhancer (www.energinat.com) b) 100MW OTEC platform designed for deployment off Honolulu (www.oteci.com) c) Land based production facility combining OTEC energy freshwater, agriculture and mariculture production planned for Haiti.](image)

Many of the listed deepwater utilisation techniques seem to be rather in a state of realisation than development. Deepwater cooling of urban air-conditioning is practiced since decades and the
first 10MW OTEC power plant is about to be constructed (Lusk, 2013). Deliberate eutrophication of oligotrophic tropical coastal waters evoking intuitive denegation by marine ecologists is presented as a “green” strategy for self-sustained renewable energy and food supply for the developing world. The Haitian “Energinat” cooperation, supported by several international companies among others Lockheed Martin, a large US armaments concern, concludes on its homepage (www.energinat.com):

“In our opinion the sustainable socioeconomic development of Haiti can only take place in a harmonious, secure and politically stable environment and will not happen unless Haitians exploit their deep ocean water resource – the nation’s most valuable natural energy resource and its inexhaustible marine gold mine. THERE IS NO ALTERNATIVE. THERE IS NONE.”

Possible ecological risks of eutrophication such as toxic algal blooms or coral reef destruction spontaneously coming to mind are not discussed. Plans to cover energy requirements of Hawaii by offshore OTEC presented by OTEC international LCC (www.oteci.com) appear somewhat more down to earth. Here, potential ecological impacts of artificial upwelling are discussed in the FAQ section as “potentially increasing the food source for surrounding marine live”. A 100 MW plant five miles off Honolulu is planned.

Offshore OTEC in combination with mariculture could be a promising strategy to cover a rising demand for renewable energy and quality food. At the same time it could provide a perpetual source of income to less developed coastal nations that are otherwise poor in resources.

Governmental funding of research on tropical upwelling events seems probable as mesocosm experiments could help to provide a data basis for risks and benefit estimates of such approaches, which would help policy makers to create a legal basis for sustainable use of marine engineering. A pilot study employing free drifting KOSMOS mesocosms was successfully conducted in the Pacific off Hawaii in 2011. Scientific capacity building in less developed countries such as Haiti could improve on-site abilities to judge the installation of unapproved technologies in their local coastal waters.

4.6 References Perspectives

Contribution of authors

Technical Note: A mobile sea-going mesocosm system – new opportunities for ocean change research.

Klaus von Bröckel, Ulf Riebesell and Kai Schulz conceived the original design; Uwe Lentz, Detlef Hoffmann and Ronald Muche gave technical input, designed and constructed prototype mesocosms. Ulf Riebesell, Jan Czemy, Klaus von Bröckel, Kai Schulz and Sebastian Krug contributed conceptual ideas for the development of the mesocosms to operational readiness. Detailed technical design and accomplishment was performed by Detlef Hofmann, Uwe Lentz, Jan Czemy, Ronald Muche and Mario Deckelnick. Andrea Ludwig and Sebastian Krug managed the logistics of the deployments and experiments. Jan Büdenbender, Jan Czemy, Sebastian Krug and Matthias Fischer planned and performed underwater constructions and connected logistics. Within regular meetings, all authors contributed important ideas concerning all aspects during the development of KOSMOS. Ulf Riebesell wrote the manuscript. Jan Czemy, Klaus von Bröckel, Tim Boxhammer, Jan Büdenbender and Kai Schulz assisted with input to the manuscript and revision.

Technical Note: The determination of enclosed water volume in large flexible-wall mesocosms “KOSMOS”
J. Czemy, K. G. Schulz, S. A. Krug, A. Ludwig, and U. Riebesell

Jan Czemy, Kai Schulz, Sebastian Krug, Andrea Ludwig and Ulf Riebesell developed the idea. Jan Czemy designed the experimental set-up and performed experiments together with Kai Schulz, Sebastian Krug, Andrea Ludwig and Ulf Riebesell. Jan Czemy wrote the manuscript. Kai Schulz and Ulf Riebesell assisted with input to the manuscript and revision.
Technical Note: A simple method for air-sea gas exchange measurements in mesocosms and its application in carbon budgeting
J. Czemy, K. G. Schulz, A. Ludwig, and U. Riebesell

Jan Czemy, Kai Schulz, Andrea Ludwig and Ulf Riebesell developed the idea. Jan Czemy designed the experimental set-up and performed experiments with the help of Kai Schulz, Andrea Ludwig and Ulf Riebesell. Jan Czemy wrote the manuscript. Kai Schulz and Ulf Riebesell assisted with input to the manuscript and revision.

Sediment sample processing
J. Czemy, T. Boxhammer, K. von Bröckel, A. Ludwig, and U. Riebesell

Jan Czemy, Ulf Riebesell, Klaus von Bröckel and Andrea Ludwig developed the idea. Jan Czemy designed the experimental set-up. Tim Boxhammer and Jan Czemy developed the method until operational. Tim Boxhammer performed measurements. Jan Czemy wrote the article. Tim Boxhammer assisted with input and revision.

Implications of elevated CO2 on pelagic carbon fluxes in an Arctic mesocosm study – an elemental mass balance approach

Ulf Riebesell, Kai Schulz, Jan Czemy, Andrea Ludwig, Sebastian Krug, Jan Büdenbender, Tim Boxhammer, Richard Bellerby, Kerstin Nachtigall, Gisle Nondal, Barbara Niehoff and Anna Silyakova performed the experiment. Kai Schulz, Jan Czemy, Andrea Ludwig, Sebastian Krug, Tim Boxhammer, Richard Bellerby, Kerstin Nachtigall, Gisle Nondal, Barbara Niehoff, Anna Silyakova and Anja Engel did measurements. Jan Czemy analysed the data and wrote the manuscript. Ulf Riebesell, Kai Schulz, Jan Büdenbender, Tim Boxhammer, Richard Bellerby, Gisle Nondal, Barbara Niehoff and Anna Silyakova assisted with input to the manuscript and revision.
Danksagung

Eric danke ich für seine zügige Erstellung des Zweitgutachtens und den übrigen Komiteemitgliedern für Ihre Mitarbeit im Prüfungsausschuss.

Meiner Mutter danke ich, für Ihre bedingungslose und liebevolle Unterstützung, die sie mir auf meinem gesamten Lebensweg, besonders auch während meiner Schulzeit, hat zukommen lassen.

Seit meiner frühen Kindheit war mein Vater Vorbild und Diskussionspartner in naturwissenschaftlich-technischen Fragen und hat meine Interessen in diesem Bereich maßgebend gefördert. Auch heute greife ich zeitweise auf seinen umfassenden verfahrenstechnischen Überblick zurück. Er ist jederzeit bereit, sich mit meinen Ideen zu befassen, sie zu begreifen und rechnerisch so zu erfassen, dass sie dann so funktionieren wie angedacht.

Die Listen der Autoren auf unseren Publikationen sind lang. Mit den allermeisten war es eine Freude zusammen zu arbeiten oder zusammen zu forschen. Ich bin allen zum Dank verpflichtet, einige will ich aber hier hervorheben.

Ich danke Tim, da ich und wahrscheinlich auch sonst niemand die Geduld gehabt hätte, vergleichbare Ansprüche an Präzision in der Sedimentanalyse zu erfüllen.

Von Kai Schulz habe ich im wissenschaftlichen Bereich am meisten profitiert. Er hat sich immer die Zeit zum Diskutieren genommen, wenn man bei ihm ins Büro gestolpert ist. Auch beim Rotwein morgens um fünf, konnte man noch etwas lernen.

Wo ich gerade bei den Mentoren bin … Joana hat mich geprägt!
Wenden wir uns der technischen Seite zu: Uwe und Klaus verkörpern den wissenschaftlich-technischen Erfahrungsschatz, von dem ich sehr profitiert habe.

Ronald ist hervorzuheben, er ist so etwas wie der „Jedi-Meister des Hammers und der Schraube“. Ronald kann alles und zeigte es auch geduldig jemandem mit so beschränktem technischen Grundwissen wie mir.

Besondere Freunde und Kollegen sind natürlich alle unsere Taucher! Wir haben zusammen gefroren und gekämpft! Jan, Matze und Sebastian, aber auch alle die später dazukamen, ihr seid die besten, jeder auf seine eigene unterschiedliche Art!

Benni und Gerd, ihr habt einen ganz besonderen Dank verdient, weil ich mit euch mal über etwas anderes rede als über den „Wanderzirkus“. Ich hoffe, das wird bald wieder häufiger!
Eidesstattliche Erklärung

Kiel, den 24.01.14

Jan Czerny
