We quantify the oceanic sink for anthropogenic carbon dioxide (CO₂) over the period 1994 to 2007 by using observations from the global repeat hydrography program and contrasting them to observations from the 1990s. Using a linear regression–based method, we find a global increase in the anthropogenic CO₂ inventory of 34 ± 4 petagrams of carbon (Pg C) between 1994 and 2007. This is equivalent to an average uptake rate of 2.6 ± 0.3 Pg C year⁻¹ and represents 31 ± 4% of the global anthropogenic CO₂ emissions over this period. Although this global ocean sink estimate is consistent with the expectation of the ocean uptake having increased in proportion to the rise in atmospheric CO₂, substantial regional differences in storage rate are found, likely owing to climate variability–driven changes in ocean circulation.

Detecting the change in anthropogenic CO₂

We use the data synthesized by the Global Ocean Data Analysis Project version 2 (GLODAPv2) (8) and the recently developed eMLR(C*) method (9) to identify the change in Cₐnt (ΔCₐnt) between the WOCE-JGOFS (nominal 1994) and the Repeat Hydrography–GO-SHIP (nominal 2007) periods (see supplementary materials for details, figs. S3 to S5). This method builds on the extended multiparameter linear regression (eMLR) approach (20), which was designed to separate ΔCₐnt from any natural CO₂-driven change in dissolved inorganic carbon. The eMLR(C*) method has been extensively tested with synthetic data from a biogeochemical model (9), demonstrating its ability to reconstruct ΔCₐnt with high accuracy at global and basin scales. These tests also revealed that subbasin scales are less well resolved, especially in regions characterized by high temporal variability. To quantify the uncertainties in the reconstructions, we used the spread from a Monte Carlo analysis and an ensemble of 14 sensitivity studies (see supplementary materials for details).

Global distribution

The global, vertical distribution of ΔCₐnt between 1994 and 2007 reveals the strong gradients that are characteristic for a passive conservative tracer invading the ocean from the surface (Fig. 1). In the upper 100 m, Cₐnt increased, on average, by 14 μmol kg⁻¹ over this period, close to the expected level given the rise in atmospheric CO₂ and the ocean’s buffer capacity (11). Below that, ΔCₐnt decreases rapidly with depth, reaching half of the surface value at 375 m and 1/10 of it at 1000 m. Half of the global ΔCₐnt signal is found in the top 400 m, more than 75% above 1000 m, and only about 7% between 2000 and 3000 m.

There are strong spatial variations in the vertical penetration of ΔCₐnt (Fig. 1), reflecting the differences in the efficiency with which the surface signal is transported and mixed down by the large-scale overturning circulation (1, 3, 12–14). As transport occurs primarily along sloping neutral density surfaces (15), it is instructive to investigate the distribution of ΔCₐnt on such isosurfaces (Fig. 2). The relatively shallow surfaces associated with mode waters (such as the neutral surface 26.60 kg m⁻³) (16) are ventilated on time scales of a few decades or less, such that the anthropogenic CO₂ signal is transported rather effectively from the outcrops at the mid to high latitudes toward the ocean’s interior (Fig. 2A). By contrast, substantial changes in Cₐnt on the deeper (~1000 m in the mid and low latitudes) 27.40 kg m⁻³ neutral surface are essentially limited to the regions close to the outcrop (Fig. 2B). This reflects the decade- to century-long ventilation ages of the water masses occupying this neutral surface, consisting, in the Southern Hemisphere, primarily of Antarctic Intermediate Water. Despite its limited horizontal reach, the downward transport of the ΔCₐnt signal along this neutral surface from the Southern Ocean outcrop leads to the second-deepest penetration of ΔCₐnt anywhere in the ocean (Fig. 1). The deepest penetration is found in the North Atlantic, where the downward spreading of newly formed North Atlantic Deep Water (NADW) causes a ΔCₐnt with a maximum of 5 μmol kg⁻¹ below 1000 m. The rapid southward spreading of NADW between about 1500 and 2500 m transports this elevated ΔCₐnt into the South Atlantic. The corresponding process is much less vigorous and deep-reaching in the North Pacific, as there is no deep-water formation there. This leads to a shallow penetration by mode and intermediate waters.

These regional differences in the vertical penetration cause large spatial variations in the column inventory of ΔCₐnt. The change in Cₐnt integrated vertically from the surface down to 3000 m (Fig. 3A). Large parts of the mid-latitude North Atlantic increased their anthropogenic CO₂ loads by 16 ± 1 mol C m⁻² or more between 1994 and 2007. This corresponds to an average
storage rate of $1.2 \pm 0.1 \text{ mol m}^{-2} \text{ year}^{-1}$; twice the global mean storage rate of $0.65 \pm 0.08 \text{ mol m}^{-2} \text{ year}^{-1}$. Large changes are also found along a broad zonal band in the mid-latitudes of the Southern Hemisphere, with maximum values above $15 \pm 2 \text{ mol m}^{-2}$ throughout much of the South Atlantic, and progressively smaller values going eastward into the Indian and Pacific Oceans. This reflects the deep, but spatially variable, penetration of $\text{C}_{\text{ant}}$ into the thermoclines of these basins induced by downward transport by mode and intermediate waters (17, 18) (compare Fig. 1), i.e., the upper cell of the meridional overturning circulation in the Southern Hemisphere (19).

In contrast to the regions with high accumulation, the low column inventory changes in the region south of $60^\circ$S stand out. The average change in storage there is less than $4 \pm 2 \text{ mol m}^{-2}$, corresponding to a rate of only $0.30 \pm 0.15 \text{ mol m}^{-2} \text{ year}^{-1}$, i.e., less than half of the global mean. This low storage rate is associated with the lower cell of the meridional overturning circulation (19). First, the upwelling of old waters with low concentrations of $\text{C}_{\text{ant}}$ (compare Fig. 1) around the Antarctic Polar Front prevents a substantial accumulation of $\text{C}_{\text{ant}}$ there. Second, there is little downward transport associated with the downward component of the lower cell, likely owing to the physical blocking of the air-sea exchange of $\text{CO}_2$ by sea ice in the Antarctic zone and the relatively short residence time of these waters at the surface (20). This contrasts strongly with the upper overturning cell, which takes up a lot of anthropogenic $\text{CO}_2$ from the atmosphere but quickly transports it northward into the band of high storage between $50^\circ$S and $30^\circ$S (14, 17, 21).

**Global and regional inventory change**

Integrated globally and down to a depth of $3000 \text{ m}$, we estimate a change in the inventory of oceanic anthropogenic $\text{CO}_2$ of $31.2 \pm 4 \text{ Pg C}$ for the period 1994 to 2007 (Table 1 and table S3). To this we add the uptake and storage by regions outside our gridded domain, namely, the Mediterranean Sea and the Arctic Ocean, which are estimated to account for $\sim 1.5 \text{ Pg C}$ (22–24). We add an additional $\sim 1 \text{ Pg C}$ to our estimate to account for the accumulation of $\text{C}_{\text{ant}}$ below $3000 \text{ m}$, estimated from the fraction modeled for the 1994 to 2007 period (14). This yields a global oceanic storage increase of anthropogenic $\text{CO}_2$ of $34 \pm 4 \text{ Pg C}$, which equals a mean annual uptake rate of $2.6 \pm 0.3 \text{ Pg C year}^{-1}$ over the 1994 to 2007 period.

The individual ocean basins and hemispheres contribute very differently to both the global inventory and its uncertainty (Table 1). Between the hemispheres, the majority (60 ± 11%) of the increase in $\text{C}_{\text{ant}}$ is found in the Southern Hemisphere (Table 1). Between the basins, the storage in the Pacific (39 ± 4%) and Atlantic (35 ± 4%) has increased by roughly equal amounts, whereas the contribution of the Indian Ocean is much smaller (21 ± 10%).

Adding the $34 \pm 4 \text{ Pg C}$ increase between 1994 and 2007 to the $118 \pm 19 \text{ Pg C}$ estimated for the change between the preindustrial period and 1994 (1) yields a global ocean storage for 2007 of $152 \pm 20 \text{ Pg C}$. Extrapolating this estimate linearly to the year 2010 gives an inventory of $160 \pm 20 \text{ Pg C}$, which is consistent with the “best” estimate provided by Khatiwala et al. (13) of $155 \pm 31 \text{ Pg C}$, obtained by combining models and other constraints. Our estimate confirms also the results of a recent diagnostic model.
(14), which simulated a cumulative storage of about 155 to 161 Pg C for 2010. Our estimate stands out by its use of inorganic carbon measurements as the foundation to determine anthropogenic CO2 inventories, whereas the other referenced studies employed indirect or model-based methods. Our approach also implicitly includes the effect of a time-changing ocean circulation, whereas the indirect estimates of (14, 26) assume a steady-state ocean circulation.

The eMLR(C*)-based estimates of \( \Delta C_{\text{ant}} \) compare overall well with other regional data-based analyses of the change in anthropogenic CO2 conducted so far, both in terms of the vertical distributions and the column inventories (see supplementary materials). Our data-based storage rates for the period 1994 to 2007 are also in good agreement with those recently inferred from a diagnostic model of the ocean circulation (21) (fig. S6).

**Table 1. Change in the inventory of anthropogenic CO2 between 1994 and 2007 as estimated on the basis of the eMLR(C*) method.** Shown in italics are the estimated uncertainties based on the sensitivity and Monte Carlo analyses.

*Includes an estimated 1 Pg C to account for the accumulation below 3000 m, with 0.7 Pg C allocated to the North Atlantic and 0.3 Pg C to the South Atlantic (see main text). †Estimated storage in the Arctic and Mediterranean Sea (see supplementary materials).

**Fig. 2. Distribution of the change in anthropogenic CO2, \( \Delta C_{\text{ant}} \), between 1994 and 2007 on two selected neutral surfaces.**

(A) \( \Delta C_{\text{ant}} \) on the neutral surface 26.60 kg m\(^{-3}\), representing subtropical mode waters and located around 400-m depth in the centers of the subtropical gyres. (B) \( \Delta C_{\text{ant}} \) on the neutral surface 27.40 located at a depth of about 1000 m. In the Southern Hemisphere and in the Indian and Pacific oceans, this neutral surface represents southern-sourced Antarctic Intermediate Water, whereas in the North Atlantic it represents Intermediate Water formed in the north. Stippled areas poleward of the highest concentration of \( \Delta C_{\text{ant}} \) indicate the outcrop areas of these neutral surfaces. Hatched areas indicate regions where no estimate of \( \Delta C_{\text{ant}} \) was possible owing to data limitations.

**Comparison with the JGOFS-WOCE era reconstructions**

The column inventory change between 1994 and 2007 (Fig. 3A) is spatially well correlated \( (r^2 = 0.68) \) with the total inventory of anthropogenic CO2 in 1994 (Fig. 3B) (1). This relationship is consistent with the nearly exponential and multi-decadal nature of the anthropogenic perturbation of the global carbon cycle, which results in the establishment of a “transient steady state” (27).

For an ocean with invariant circulation and mixing, this transient steady state implies that the change of anthropogenic CO2 over any time period \( t_1 \) to \( t_2 \) is linearly related to the amount of anthropogenic CO2 at the initial time, \( t_1 \), i.e., \( \Delta C_{\text{ant}}(t_2 - t_1) = \alpha \cdot C_{\text{ant}}(t_1) \) (28). We estimate the proportionality \( \alpha \) from theoretical considerations for the period 1994 through 2007 and obtain a value of \( \alpha = 0.28 \pm 0.02 \) (see supplementary materials). This value varies little by region, but it varies substantially over time. This theoretically estimated value is statistically indistinguishable from the ratio of the global change in inventory between 1994 and 2007 (34 ± 4 Pg C) and the inventory in 1994 (118 ± 19 Pg C). This implies that, to first order, the global ocean has continued to take up anthropogenic CO2 from the atmosphere at a rate expected...
from the increase in atmospheric CO2, i.e., there is no indication of a major change in the uptake over the 1994 to 2007 period relative to the long-term mean.

On a regional basis, however, the reconstructed distribution of $\Delta C_{\text{cant}}$ differs from that inferred from the $C_{\text{cant}}$ distribution in 1994 and the assumption of a transient steady state (Fig. 3C). We interpret these differences, i.e., the anomalous accumulation of $C_{\text{cant}}$ ($\Delta C_{\text{cant}}^{\text{anom}} = \Delta C_{\text{cant}} - \alpha C_{\text{cant}}$) to be primarily the result of variations in ocean circulation. But care must be taken when interpreting $\Delta C_{\text{cant}}^{\text{anom}}$, because the associated uncertainties accumulate the errors from all terms, i.e., $\Delta C_{\text{cant}}$, $\alpha$, and $C_{\text{cant}}$. As shown in the supplementary materials, the most important source of error is the reconstruction of $\Delta C_{\text{cant}}$ itself. In particular, tests with synthetic data from an ocean biogeochemical model showed that although the eMLR(C*) method generally works well, changes in ocean circulation tend to lead to biases in the reconstructed $\Delta C_{\text{cant}}$, which directly affect the inferred $\Delta C_{\text{cant}}^{\text{anom}}$ (9). However, these tests also revealed that the method is still able to recover the most important signals associated with $\Delta C_{\text{cant}}^{\text{anom}}$, especially in the North Atlantic. The error is largest in the North Pacific, yet across the globe, more than 50% of the modeled variance in $\Delta C_{\text{cant}}^{\text{anom}}$ at basin scales is correctly recovered. Globally, the bias of the recovered $\Delta C_{\text{cant}}^{\text{anom}}$ is essentially zero.

The most prominent anomaly is found in the North Atlantic, where the reconstructed change

**Fig. 3.** Maps of the column inventories of anthropogenic CO2 in the ocean (0 to 3000 m). (A) Change in column inventory between 1994 and 2007 based on the eMLR(C*) method. (B) Column inventory for the year 1994 (i) based on the $\Delta C^*$ method (45). (C) Anomalous change in column inventory estimated from the difference between the change in the vertical column inventory [shown in (A)] and that expected on the basis of the transient steady-state model and the $C_{\text{cant}}$ inventory [shown in (B)], namely, $\Delta C_{\text{cant}}^{\text{anom}} = \Delta C_{\text{cant}} - \alpha C_{\text{cant}}(1994)$, $\alpha = 0.28$. The column inventories were obtained by vertically integrating the values from the surface down to 3000 m. Hatched areas indicate regions where no estimate of $\Delta C_{\text{cant}}$ was possible owing to data limitations.
in inventory over the entire basin is 20% smaller than that predicted by the transient steady state (Fig. 3C). This anomaly, likely robust given that it was well recovered in the tests with synthetic data, characterizes nearly the entire water column (Fig. 4A). The strongest $\Delta C_{\text{ant}}$ anomalies are found in the subpolar gyre and within the Subpolar Mode Water and in the Intermediate Water, both belonging to the water masses with the highest burden of anthropogenic CO2 ($10^{12}, 29$). This lower-than-expected increase in storage in the North Atlantic during the 1990s and early 2000s has been described previously ($29-31$) and was attributed to the slow-down and reorganization of the North Atlantic overturning circulation at that time, which led to a reduction in the downward transport of $C_{\text{ant}}$ ($29, 31$). This slowdown was probably temporary, as indicated by the more recent rapid increase in $C_{\text{ant}}$ in the Irminger Sea ($32$).

The anomalously low accumulation in the North Atlantic between 1994 and 2007 co-occurred with an anomalously high accumulation in the South Atlantic, such that the storage change of the entire Atlantic remained very close to the expected one. Even though we are somewhat less confident about the reconstructed $\Delta C_{\text{ant}}$ in the South Atlantic given our tests with synthetic data ($9$), we point out that such a shift in storage from the Northern to the Southern Hemisphere was seen in previous $\Delta C_{\text{ant}}$ reconstructions, albeit based on a single meridional section ($30$).

A second set of major regions of anomalous change in inventory are the Indian and Pacific sectors of the Southern Ocean, where the changes in storage are about 20% lower than expected (Fig. 3C). The tests with synthetic data showed that changes in these regions should be captured by the eMLR(C*)-based reconstruction, although likely underestimated ($9$). We have some confidence in the robustness of this signal because it is caused by a negative $\Delta C_{\text{ant}}$ anomaly that is confined to the neutral density layers of Antarctic Intermediate Water and found in all ocean basins (Fig. 4). We interpret this signal to be the result of the southward movement and strengthening of the westerly wind belt ($33$), which has caused large-scale coherent changes...
in the meridional overturning circulation in the Southern Ocean and the ventilation of the water masses (34, 35). Further, the wind changes have caused increased upwelling over the Southern Ocean and enhanced Ekman transport to the north, leading to shorter residence times of waters at the surface. This could have led to the weaker uptake and consequently weaker downward transport of anthropogenic CO₂ into the thermocline by the upper cell of the meridional overturning circulation, leading to the observed negative ΔC_{\text{nat}}^{\text{anom}} in the Antarctic Intermediate Water.

Additional support of our interpretation that the reconstructed ΔC_{\text{nat}}^{\text{anom}} are real stems from the overall agreement of our result with those inferred recently from a diagnostic ocean model (27). Although our changes are somewhat larger, the patterns agree well and support the conclusion that the changes primarily reflect changes in ocean circulation.

Implications

Our reconstructed changes in the oceanic inventory of anthropogenic CO₂ imply a continuing strong role of the ocean in the recent global carbon budget (Table 2). From 1994 to 2007, anthropogenic emissions added 110 ± 8 Pg C to the atmosphere (36), most of which stemmed from the burning of fossil fuels (94 ± 5 Pg C) (3). Of these emissions, 50 ± 1 Pg C (45%) remained in the atmosphere (37). Our uptake estimate of 34 ± 4 Pg C implies that the ocean accounts for the removal from the atmosphere of 31 ± 4% of the total anthropogenic CO₂ emissions over this time period (Table 2). This anthropogenic CO₂ uptake fraction does not differ from that for the period from preindustrial times up to 1994 (1).

Our ocean uptake estimate for anthropogenic CO₂ permits us also to provide a constraint on the net land uptake for the 1994 through 2007 period. This requires us to consider also the potential contribution of a small anomalous (non-steady state) net flux of natural CO₂, emerging from processes such as ocean warming and climate variability–driven changes in ocean circulation and biology (38). We obtain a rough estimate of this contribution by using the surface ocean partial pressure of CO₂ (pCO₂)–based air-sea flux estimate of (39) for the 1994 through 2007 period and subtracting from it the expected anthropogenic uptake flux consistent with (37), while accounting also for the steady-state outgassing of natural CO₂. This yields a cumulative anomalous net release of natural CO₂ of about 5 ± 3 Pg C. The resulting net (natural and anthropogenic CO₂) ocean uptake estimate of 29 ± 5 Pg C for the 1994 through 2007 period implies a net terrestrial biospheric sink over this period of 31 ± 9 Pg C, or about 2.9 ± 0.7 Pg C year⁻¹ (Table 2). Our data-based net ocean uptake estimate confirms the model-based 26 ± 4 Pg C ocean sink reported by the Global Carbon Project over the 1994 through 2007 period (36).

Although the ~30% increase in the oceanic burden of anthropogenic CO₂ between 1994 and 2007 constitutes a great service for humanity by slowing down the accumulation of CO₂ in the atmosphere, this service comes with the cost of increased oceanic acidification (40). Our reconstructed increases in C_{\text{nat}} imply a deep reach of ocean acidification into the ocean’s interior (41, 42), causing a further shoaling of the ocean’s saturation horizons for biogenic carbonate minerals (43), and a further squeezing of the available habitats for the organisms sensitive to changes in the ocean’s CO₂ chemistry (40, 44).

Documenting and quantifying these changes in anthropogenic CO₂ and ocean acidification require the continuation of whole-ocean observations of inorganic carbon and of the many ancillary variables needed to produce the internally consistent data products that are so crucial for analyzing long-term changes in ocean carbon storage. In addition, the continuing documentation of the biogeochemical and physical changes in the ocean will be essential for understanding any forthcoming changes in ocean biology.

The oceanic sink for anthropogenic CO₂ from 1994 to 2007

Science 363 (6432), 1193-1199.
DOI: 10.1126/science.aau5153

The state of ocean CO₂ uptake

The ocean is an important sink for anthropogenic CO₂ and has absorbed roughly 30% of our emissions between the beginning of the industrial revolution and the mid-1990s. This effect is an important moderator of climate change, but can we count on it to remain as strong in the future? Gruber et al. calculated the ocean uptake of anthropogenic CO₂ for the interval from 1994 to 2007, which continued as expected. They also observed clear regional deviations from this pattern, suggesting that there is no guarantee that uptake will remain as robust with time.

Science, this issue p. 1193
