Abstract. Climate change in Siberia is currently receiving a lot of attention because large permafrost-covered areas could provide a strong positive feedback to global warming through the release of carbon that has been sequestered there on glacial–interglacial timescales. Geological evidence and climate model experiments show that the Siberian region also played an exceptional role during glacial periods. The region that is currently known for its harsh cold climate did not experience major glaciations during the last ice age, including its severest stages around the Last Glacial Maximum (LGM). On the contrary, it is thought that glacial summer temperatures were comparable to the present day. However, evidence of glaciation has been found for several older glacial periods.

We combine LGM experiments from the second and third phases of the Paleoclimate Modelling Intercomparison Project (PMIP2 and PMIP3) with sensitivity experiments using the Community Earth System Model (CESM). Together, these climate model experiments reveal that the intermodel spread in LGM summer temperatures in Siberia is much larger than in any other region of the globe and suggest that temperatures in Siberia are highly susceptible to changes in the imposed glacial boundary conditions, the included feedbacks and processes, and to the model physics of the different components of the climate model. We find that changes in the circumpolar atmospheric stationary wave pattern and associated northward heat transport drive strong local snow and vegetation feedbacks and that this combination explains the susceptibility of LGM summer temperatures in Siberia. This suggests that a small difference between two glacial periods in terms of climate, ice buildup or their respective evolution towards maximum glacial conditions can lead to strongly divergent summer temperatures in Siberia, allowing for the buildup of an ice sheet during some glacial periods, while during others, above-freezing summer temperatures preclude a multi-year snowpack from forming.

1 Introduction

During the Last Glacial Maximum (LGM; \textasciitilde 24–18 ka), ice sheets covered large parts of the Northern Hemisphere continents. Over North America and northwestern Eurasia, continental ice sheets extended from the Arctic Ocean down to \textasciitilde 40\textdegree N in some areas. A notable exception was northeastern Siberia, a region that remained largely ice free during the LGM according to archeological evidence (Pitulko et al., 2004), geological reconstructions and permafrost records (Boucsein et al., 2002; Schirrmeister, 2002; Hubberten et al., 2004; Gualtieri et al., 2005; Stauch and Gualtieri, 2008; Wettermich et al., 2011; Jakobsson et al., 2014; Ehlers et al., 2018), and combined model–data-driven ice-sheet reconstructions (Abe-Ouchi et al., 2013; Kleman et al., 2013; Peltier et al., 2015). This is intriguing given the fact that the area presently extends as far north as \textasciitilde 75\textdegree N and extended even further north during the LGM when a large part of the Siberian continental shelf was exposed because of eustatic sea-level lowering.

Reconstructing Quaternary ice-sheet limits and assigning geological ages has for various reasons proven to be a difficult task for the Siberian region (e.g., Jakobsson et al., 2014). Svendsen et al. (2004) synthesized the existing geological data and concluded that since the penultimate glacial period (\textasciitilde 140 ka), most of Arctic Siberia has remained ice free, with the exception of the high-altitude Putorana Plateau.
and the coastal areas of the Kara Sea. Independent evidence from permafrost records (Boukein et al., 2002; Schirrmeister, 2002; Hubberten et al., 2004; Wetterich et al., 2011), marine sediment cores (Darby et al., 2006; Polyak et al., 2004, 2007, 2009; Adler et al., 2009; Backman et al., 2009) and dating of mollusk shells (Basilyan et al., 2010) also indicates that the entire region between the Taymyr Peninsula and the Chukchi Sea remained ice free and was covered by tundra-steppe during the LGM and that the last grounded ice impacts in different sectors of this region date back to Marine Isotope Stage 6 (MIS 6) or potentially MIS 5 within the dating uncertainties (Stauch and Gualtieri, 2008). Hence, the existing geological evidence indicates that ice sheets covered large parts of western Siberia (Svendsen et al., 2004; Patton et al., 2015; Ehlers et al., 2018) and the east Siberian continental shelf (Niessen et al., 2013; Jakobsson et al., 2014, 2016) prior to the last glacial period, but it remains unclear how often northeastern Siberia experienced large-scale glaciations during the different glacial periods of the Quaternary. Nonetheless, it appears that this far northern region was covered by ice during some glacial periods, while it remained ice free during others.

A number of studies have simulated the eastern Siberian LGM climate and ice-sheet growth (e.g., Krinner et al., 2006; Charbit et al., 2007; Ganopolski et al., 2010; Abe-Ouchi et al., 2013; Beghin et al., 2014; Peltier et al., 2015; Liakka et al., 2016). They show widely different results, from ice-free conditions to the buildup of a large ice sheet covering most of Siberia, and therefore the correspondence with proxy-based reconstructions ranges from good to very poor.

Over the years, a number of possible mechanisms have been suggested to explain the lack of an ice sheet covering eastern Siberia during the LGM and perhaps therewith also explain the divergent results of coupled climate–ice-sheet simulations for this region during the LGM. The most widely discussed mechanisms involve changes in atmospheric dust load, orographic precipitation effects and/or changes in atmospheric circulation driven by the buildup of the North American and/or Eurasian ice sheets.

During glacial times, the atmospheric dust load and dust deposition were likely substantially larger, particularly at the southern margins of the Northern Hemisphere ice sheets and over Siberia (Harrison et al., 2001; Lambert et al., 2015; Mahowald et al., 1999, 2006). Modeling studies have shown that the buildup of ice over Siberia can be strongly impacted by the effect of dust on the surface albedo as an increase of dust deposition on the snowpack leads to a lowering of the snow albedo that in turn leads to higher melt rates (Krinner et al., 2006; Willeit and Ganopolski, 2018).

Continental ice sheets have a strong impact on the climate. It was already recognized by Sanberg and Oerlemans (1983) that under the influence of a preferred wind direction, an ice sheet can create a distinct asymmetry with high precipitation rates at the windward side and low precipitation rates on the leeward side. This precipitation shadow effect has also been proposed as an explanation for a westward migration of the Eurasian ice sheets during the last glacial period (Liakka et al., 2016, and references therein). Through the precipitation shadow effect, the buildup of the Eurasian ice sheet would lead to dry conditions in Siberia and potentially prevent the buildup of an ice sheet in the area.

Another way in which ice sheets can impact the climate is through their steering effect on the large-scale atmospheric circulation. Broccoli and Manabe (1987) showed that the buildup of the North American ice sheets leads to substantial changes in the midtropospheric flow, including a split of the jet stream around the northern and southern edges of the ice sheet and a resulting increase of summer temperatures over Alaska. Similar impacts of glacial ice sheets on large-scale atmospheric circulation were found in a number of other modeling studies (e.g., Cook and Held, 1988; Roe and Lindzen, 2001; Justino et al., 2006; Abe-Ouchi et al., 2007; Langen and Vinther, 2009; Liakka and Nilsson, 2010; Ullman et al., 2014; Liakka et al., 2016). Generally, these studies indicate a warming over Alaska as a result of the growth of the North American ice sheets, but it differs from one study to the next how far westward this warming extends into Siberia. In these modeling studies, the warming in Alaska and Siberia is linked to increased poleward heat transport induced by changes in the atmospheric stationary waves and to local feedbacks involving the surface albedo and atmospheric water vapor content (Liakka and Lofverstrom, 2018). A compilation of LGM temperature reconstructions based on various land proxy data provides support to these inferences, showing that LGM summer temperatures in northern Siberia were overall not very different from the relatively mild present-day summer temperatures in the region (Meyer et al., 2017).

The lack of an LGM ice cover in northeastern Siberia has often been attributed to the increased atmospheric dust load and/or a precipitation shadow effect of the Eurasian ice sheet to the west. However, based on these mechanisms alone, one cannot readily explain the absence of a Siberian ice sheet in some glacial periods, but its presence in others, or reconstructions of Siberian LGM summer temperatures close to present-day values (Meyer et al., 2017), suggests that these processes are likely only part of the story. Existing and new coupled climate model results can shed light on these intriguing geological observations. Here, we show that the intermodel spread of simulated LGM summer temperatures is exceptionally large in Siberia compared to any other region, suggesting a high susceptibility of Siberian summer temperatures to minor changes in boundary conditions or model formulation, and discuss potential underlying mechanisms and causes. We argue that this high susceptibility of Siberian summer temperatures to boundary conditions (hypersensitivity) is a major factor for the absence or presence of ice sheets in different Quaternary glacials.
2 Methodology

In this study, we combine LGM simulations from the second and third phases of the Paleoclimate Modelling Intercomparison Project (PMIP2 and PMIP3) with LGM sensitivity experiments using the Community Earth System Model (CESM).

2.1 PMIP experiments

We use 17 LGM coupled climate model simulations from PMIP2 and PMIP3/CMIP5 (Table 1; Braconnot et al., 2007; Harrison et al., 2015) and their corresponding pre-industrial (PI) control simulations as a reference. LGM boundary conditions follow the PMIP2 and PMIP3 protocols and include reduced greenhouse-gas concentrations, changed astronomical parameters, prescribed continental ice sheets and a lower global sea level. Nearly half (7 out of 17) of these simulations include dynamic vegetation, while the remaining use prescribed PI vegetation (Table 1). See https://pmlp2.lsce.ipsl.fr (last access: 14 February 2020) and https://pmlp3.lsce.ipsl.fr (last access: 14 February 2020) for further details and references. The analysis of PMIP model output is based on climatological means, and all output was regridded to a common 0.9° × 1.25° horizontal resolution. In order to compare the sea-level pressure results from different models and between PI and LGM, we removed the respective global mean before calculating the anomalies. For the analysis of geopotential height fields, only 16 instead of 17 PMIP models are used because PMIP2 LGM geopotential height from ECHAM5-MPIOM was not available to us.

2.2 CESM experiments

To study the simulated LGM temperatures in the Siberian region in more detail and to isolate individual mechanisms, we analyzed a number of sensitivity experiments performed with the state-of-the-science coupled climate model CESM (version 1.2; Hurrell et al., 2013). The model includes the Community Atmosphere Model (CAM), Community Land Model (CLM4.0), the Parallel Ocean Program (POP2) and the Community Ice Code (CICE4). In all our CESM experiments, we use a horizontal resolution of 1.9° × 2.5° in the atmosphere (finite volume core) and land, and a nominal 1° resolution of the ocean (60 levels in the vertical) and sea-ice models with a displaced North Pole.

For the CESM LGM simulations, we followed the most recent PMIP protocol (PMIP4; Kageyama et al., 2017), including greenhouse-gas concentrations (190ppm CO₂, 357 ppb CH₄ and 200ppb N₂O), orbital parameters (eccentricity of 0.019, obliquity of 22.949° and perihelion – 180° of 114.42°) and changes in the land–sea distribution and altitude due to lower sea-level (Di Nezio et al., 2016). In this study, we used as default the GLAC-1D LGM ice-sheet reconstruction (Ivanovic et al., 2016). Note that the PMIP4 CH₄ concentration of 375 ppb is slightly higher than the one used here.

In the first set of sensitivity experiments, we altered the imposed LGM ice-sheet boundary conditions. Within the framework of PMIP4, two LGM ice-sheet reconstructions are suggested as boundary conditions for the LGM experiments (Kageyama et al., 2017), namely GLAC-1D (Ivanovic et al., 2016) and ICE-6G (Peltier et al., 2015). When comparing these two ice-sheet reconstructions, we find substantial differences, especially an overall increase of the height of the North American ice sheets in ICE-6G compared to GLAC-1D and a lowering of the Eurasian ice sheet (Fig. 5a; both differences are on the order of 10% of the total ice-sheet height; for more details, see Kageyama et al., 2017). Changes in surface roughness resulting from the ice-sheet changes are highly uncertain and have not been taken into account. We performed a set of experiments to investigate the impact of these two different ice-sheet reconstructions on simulated Siberian LGM temperatures (see “continental ice sheets” set of experiments in Table 2).

In the second set of sensitivity experiments, we used two different versions of the atmosphere model, CAM4 and CAM5, to investigate the importance of the atmospheric model physics (see “atmospheric model physics” set of experiments in Table 2). CAM5 differs from its predecessor because it simulates indirect aerosol radiative effects by including full aerosol–cloud interactions. Furthermore, it includes improved schemes for moist turbulence, shallow convection and cloud micro- and macrophysics. Finally, while CAM4’s grid has 26 vertical levels, in CAM5, four levels were added near the surface for a better representation of boundary layer processes. See Neale et al. (2010) for a more detailed description of the atmospheric models used in CESM.

Furthermore, the CLM4.0 land model includes the possibility to use a representation of the carbon–nitrogen cycle and to calculate the resulting changes in leaf area index, stem area index and vegetation heights per plant functional type (Lawrence et al., 2011). These changes in the biophysical properties of the vegetation cover impact, for instance, evapotranspiration and surface albedo. Note that the spatial distribution of plant functional types is prescribed in CLM4.0, which is why the model is sometimes described as a semi-dynamic vegetation model. Nonetheless, for simplicity, we will refer to simulations that include carbon–nitrogen dynamics as “interactive vegetation” simulations in the remainder of this paper. To study the interdependency of interactive vegetation and atmospheric model physics, we performed a total of four experiments, with either CAM4 or CAM5 and including or excluding interactive vegetation, that are referred to as the “interactive vegetation” set of experiments (Table 2).

All LGM experiments performed with CESM start from a previous LGM simulation and are run for at least 200 years to obtain a new surface climate equilibrium. Carbon pools in the litter and soils take centuries to equilibrate. However, we
Table 1. List with PMIP2 and PMIP3 climate models included in the analysis with details on grid resolution and usage of interactive vegetation. In the last column, the simulated LGM June–July–August (JJA) surface temperature anomaly (K) in the Siberian target region with respect to the pre-industrial is given for reference. The following abbreviations are used: Atm (atmospheric grid resolution), Ocn (ocean grid resolution) and L (number of levels in the vertical). See https://pmip2.lsce.ipsl.fr (last access: 14 February 2020) and https://pmip3.lsce.ipsl.fr (last access: 14 February 2020) for further details and references.

find that the trends are sufficiently small after 200 years to perform a robust analysis of the surface climate. Changes in Siberian (global) vegetation carbon pools amount to less than 2% (0.6%) of the total PI–LGM change for the model years 150–200. Top-of-the-atmosphere imbalances in the simulations including the carbon–nitrogen cycle are −0.1 and −0.185 Wm⁻² using the CAM4 and CAM5 atmospheric models, respectively. Climatologies are calculated based on the last 30 years of the simulations. For the sensitivity experiments focusing on interactive vegetation and atmospheric

model physics, we also performed corresponding PI simulations (Table 2) to enable a proper analysis. Our five CESM LGM experiments are jointly referred to as the CESM LGM ensemble.

Throughout this paper, we focus on boreal summer (June–July–August; JJA) near-surface air temperatures and simply referred to them as “JJA temperatures” in the remainder of this paper. Moreover, when calculating LGM anomalies, we refer to the difference between an LGM simulation and the corresponding PMIP or CESM PI experiment (Table 2). It is in turn differences between these CESM LGM anomalies that we use to highlight mechanisms behind the susceptibility of Siberian summer temperatures (Sect. 3.2).

3 Results

3.1 Siberian LGM temperatures in PMIP2 and PMIP3 ensembles

The combined PMIP2 and PMIP3 LGM experiments reveal the particularity of LGM JJA temperatures in Siberia. Of all continental areas that were not covered by large ice sheets, Siberia shows the largest intermodel spread of LGM anomalies (standard deviation; Fig. 1b). Another striking feature of the Siberian region is that it is one of the few regions where the PMIP multi-model mean temperature anomaly is close to or even above zero in some areas, indicating that LGM summers were potentially as warm as they are at present (Fig. 1a). Taken together, PMIP simulations show LGM JJA temperatures in Siberia ranging from warmer to substantially colder than they are at present. If we define a target region for Siberia based on the area where the PMIP multi-model spread is larger than 7°C (green contours in Fig. 1; referred to as the “Siberian target region” in the remainder of the paper and located roughly between 120–180° E and 70–75° N), we see that JJA temperature anomalies averaged over the target region for the individual models range between −12 and +12°C (Fig. 2 and Table 1). The spread in simulated LGM temperatures in the Siberian target region increases compared to PI in all seasons; however, JJA really stands out (top row of Fig. A1).

Disentangling the causes of the particularity of the Siberian LGM summer temperatures based on PMIP results is not straightforward because of multiple possible underlying causes; nonetheless, some aspects can be identified. Whereas the simulated temperature changes are quite different among PMIP models, a robust decrease in precipitation on the order of 20%–30% is simulated (Fig. 1c and d). As a consequence, the (Pearson) correlation between temperature change and precipitation change in the target region is insignificant at the 0.05 significance level ($R = 0.36$; Fig. 2a; note that, throughout the paper, correlation refers to intermodel correlation). A significant correlation is found between temperature and snow cover, with higher temperatures corresponding to a lower snow cover ($R = -0.60$; $p < 0.05$; Fig. 2e). There are similarities between the spatial patterns of the PMIP multi-model spread in temperature anomalies and cloud cover anomalies (Fig. 1b and f); however, within the Siberian target region, local JJA temperature anomalies and cloud cover anomalies are not correlated at the 0.05 significance level ($R = -0.45$; Fig. 2b), arguing against a leading role of local cloud dynamics to explain the large intermodel spread in Siberian temperatures. As in Yanase and Abe-Ouchi (2007), we find that a weakening of the North Pacific high during JJA is a consistent feature of PMIP LGM simulations (Fig. 1g). Moreover, a strong
Figure 1. The PMIP2 and PMIP3 multi-model mean (left panels) and multi-model standard deviation (right panels) in LGM JJA climate anomalies. (a–b) Temperature anomalies (°C). (c–d) Precipitation anomalies (%). (e–f) Cloud cover anomalies (%); (g–h) sea-level pressure anomalies (hPa). All anomalies are calculated with respect to PI. Note that regions covered by continental ice sheets during the LGM have been masked out. The green contour (shown in magnification in the top right) shows the Siberian target region, defined here as the region in which the PMIP multi-model standard deviation is larger than 7 °C. The LGM coastlines are given in black.
Figure 2. PMIP2 and PMIP3 LGM JJA climate anomalies averaged over the northeast Siberian target region. Red (green) numbers refer to the individual PMIP2 (PMIP3) experiments listed in the lower right. (a) Precipitation anomalies (mm month\(^{-1}\)) versus temperature anomalies (\(^{\circ}\)C). (b) Cloud cover anomalies (%) versus temperature anomalies (\(^{\circ}\)C). (c) Sea-level pressure anomalies (Pa) versus temperature anomalies (\(^{\circ}\)C). (d) Sea-level pressure anomalies (Pa) versus cloud cover anomalies (%). (e) Snow cover anomalies (%) versus temperature anomalies (K). Black lines show linear fit and the \(R\) value (Pearson correlation coefficient) as listed in the lower left corners of the different subfigures. \(R\) values above 0.49 or below \(-0.49\) indicate a significant correlation (\(p < 0.05\); \(t\) test).
anticorrelation is found in the PMIP LGM simulations between JJA temperature and sea-level pressure anomalies over the Siberian target region ($R = -0.72; p < 0.05$; Fig. 2c): a more positive temperature anomaly locally creates a thermal low and hence corresponds to a less pronounced sea-level pressure anomaly. Concurrently, higher sea-level pressure anomalies correspond to more positive cloud cover anomalies ($R = 0.50; p < 0.05$; Fig. 2d). Liakka et al. (2016) found in their model that higher pressure is associated with lower cloud cover that in turn leads to an increase in JJA temperatures, but our results suggest that this is not the leading mechanism in the majority of PMIP LGM results. Inspecting the PI and LGM seasonal cycles for cloud and snow cover, we find that also for these variables the changes in intermodel spread in Siberia are most pronounced in summer. In contrast, the intermodel spread in precipitation does not change much between PI and LGM (Fig. A1).

The strong negative correlation between JJA temperature and sea-level pressure anomalies suggests that the sea-level pressure changes could be a consequence of local temperature changes. Indeed, another reason for the negative correlation could be a remote forcing through anomalous heat advection into the Siberian target region. We find evidence for such a remote forcing of the temperature variations in the Siberian target region in the significant correlation with the large-scale mid- to high-latitude stationary wave pattern, resembling a wavenumber 2 structure (Fig. 3). Increased Siberian JJA temperatures correspond to a lowering (increasing) of the JJA 500 hPa geopotential height to the southwest (southeast) of the region. The remote forcing of Siberian temperatures can thus be the result of an increase in northward-flowing relatively warm air masses over the eastern part of the Asian continent into the region of interest.

A deeper understanding of the large multi-model spread in PMIP LGM JJA temperatures over Siberia and of the mechanisms proposed above is hampered by a multitude of differences between PMIP simulations: different model formulations, different parts of the climate system that are included and different boundary conditions including the uncertainty in the reconstructed LGM ice sheet and continental outlines. Moreover, certain key climate variables are not available for a sufficiently large number of the PMIP models. In the following, we will therefore investigate a purpose-built CESM-based ensemble of LGM simulations with clearly defined differences between the individual sets of sensitivity experiments.

### 3.2 Siberian LGM temperatures in the CESM ensemble

We construct three sets of LGM sensitivity experiments performed with the CESM climate model in order to investigate in more detail the impact of changes in boundary conditions (continental ice sheets), model formulations (atmospheric model physics) and including different components of the climate system (interactive vegetation; Table 2).

Despite the fact that our total CESM LGM ensemble is smaller than the PMIP ensemble ($n = 5$ instead of $n = 17$) and that it was not designed to mimic the PMIP ensemble, we find that the spread in the CESM LGM temperature anomalies is surprisingly similar to the PMIP multi-model spread, both in terms of spatial distribution as well as magnitude (Fig. 4b). This gives us confidence that investigating the causes of the sensitivity of northeastern Siberian temperatures in the CESM ensemble can provide insights into the PMIP intermodel differences. JJA temperatures in the Siberian target region for the individual CESM experiments are listed in Table 3.

First, we analyze the first set of experiments (“continental ice sheets”), differing only in the imposed ice-sheet boundary conditions, namely LGM experiments forced by the GLAC-1D (LGM_CAM5_noVeg) or ICE-6G (LGM_CAM5_noVeg_ice6g) ice-sheet reconstructions (Table 2). On a large scale, using the GLAC-1D ice-sheet reconstruction leads to a smaller LGM JJA temperature anomaly in the Northern Hemisphere ($-6.4^\circ C$) than the simulation that includes the ICE-6G ice-sheet reconstruction ($-7.2^\circ C$; Fig. 5a). Especially in the northeastern Siberian target region, the LGM simulation using GLAC-1D ice sheets is substantially warmer ($9.0^\circ C$) compared to the simulation using ICE-6G ($6.0^\circ C$; Table 3). This can only be caused by changes in the large-scale atmospheric circulation since the simulations are identical apart from the ice sheets over North America and Eurasia. In line with the PMIP simulations, we find that higher JJA temperatures in the Siberian target region correspond to specific changes in the 500 hPa geopo-
Table 3. Simulated CESM PI and LGM climatic conditions in the Siberian target region. For the abbreviations, see Table 2. Note that LGM JJA sea-level pressure shown here has been corrected for LGM–PI differences in global mean sea-level pressure.

Figure 4. CESM ensemble mean (a) and ensemble standard deviation (b) of LGM JJA temperature anomalies (°C). Note that regions covered by continental ice sheets during the LGM have been masked out. The LGM coastlines are given in black.

The similarity of the associated temperature and geopotential height anomaly patterns (wavenumber 2 structure; Fig. 5) with the PMIP-based response (Figs. 1 and 3) suggests that this mechanism could also explain part of the spread in PMIP simulations. The anomalous northward heat transport we see in the stationary waves contributes to reinforce the (climatological) thermal low over Siberia and explains the negative relationship between JJA temperature and JJA surface pressure anomalies in the Siberian target region, both in the CESM “continental ice sheets” set of experiments (Table 3) as well as in the PMIP results (Fig. 2c).

The second set of CESM LGM simulations (“atmospheric model physics”) is comprised of simulations in which different versions of the atmospheric model were used (CAM4 or CAM5; Table 2). Between the LGM_CAM4_noVeg and LGM_CAM5_noVeg simulations, we find changes in the large-scale atmospheric circulation, in particular the stationary waves, and northward heat transport into Siberia (Fig. 6) that are broadly similar to the response to different ice sheets as described above. Similar to the analysis of the PMIP models (Fig. 3) and the CESM “continental ice sheets” set of experiments (Fig. 5), we find that using different atmospheric model physics can lead to JJA warming (cooling) in the Siberian target region in response to enhanced (decreased) meridional heat transport into northeastern Siberia. Interestingly, if we look in more detail, we find that the resulting surface temperature changes in Siberia are more complex in the “atmospheric model physics” set of experiments than they are for the experiments described previously. There is warm-
Figure 5. Impact of the prescribed LGM ice-sheet topography (GLAC-1D versus ICE-6G) on simulated LGM climate anomalies during the boreal summer season (JJA). Results are shown as the CESM experiment LGM_CAM5_noVeg minus LGM_CAM5_noVeg_ice6g. (a) Near-surface temperature anomalies (K). (b) The 500hPa geopotential height anomalies (m; anomalies calculated after subtracting the zonal mean). (c) Vertically averaged meridional sensible heat transport anomalies (K m s$^{-1}$; shading). Vectors in panel (c) show 500hPa wind anomalies (ms$^{-1}$). In panel (a), regions covered by continental ice sheets during the LGM have been masked out. The red (blue) contours in panel (a) depict positive (negative) differences in ice-sheet height (m) between the GLAC-1D and ICE-6G reconstructions (GLAC-1D – ICE-6G; 300 m contour interval). The LGM coastlines are given in black.

Figure 6. Impact of using different atmospheric models (CAM5 versus CAM4) on simulated LGM climate anomalies during the boreal summer season (JJA). Results are shown as LGM–PI anomalies for LGM_CAM5_noVeg minus LGM_CAM4_noVeg. (a) Near-surface temperature anomalies (K). (b) 500hPa stationary wave geopotential height anomalies (m; anomalies calculated after subtracting the zonal mean). (c) Vertically averaged meridional sensible heat transport anomalies (K m s$^{-1}$; shading). Vectors in panel (c) show 500hPa wind anomalies (ms$^{-1}$). In panel (a), regions covered by continental ice sheets during the LGM have been masked out. The LGM coastlines are given in black.

ing in some parts of the region but also cooling in other parts (Fig. 6a), and there are differences in the stationary wave pattern and in meridional heat transport. This is possibly related to slight shifts in the centers of action in the geopotential height anomalies and resulting changes in the air masses that enter the Siberian target region. This highlights the complexity of comparing simulations with different atmospheric model versions that not only differ in their response of the large-scale atmospheric circulation to LGM boundary conditions but also exhibit different local feedbacks with changes in cloud cover, humidity and pressure, which are directly influenced by, for instance, differences in cloud parameterizations and radiative properties of the atmosphere. This point is further exemplified by the substantial differences between CAM4 and CAM5 in Siberian JJA temperatures and snow cover under PI conditions (Table 3). The models in the PMIP ensemble all differ in the included atmospheric physics and dynamics; thus, the described mechanism in this CESM “atmospheric model physics” set of experiments could as well explain (part of) the spread within the PMIP ensemble.

An important element in the high-latitude climate system is the vegetation–climate feedback. In the PMIP ensemble, 7 out of 17 models include the vegetation–climate feedback (Table 1). However, a systematic difference in simulated JJA LGM temperature anomalies for the Siberian region could not be found when comparing models with vegetation feedback with those that did not include this additional feedback. This does not come as a surprise if one considers the relatively small sample size with respect to all the intermodel differences that impact the simulated LGM JJA temperatures. We performed PI and LGM simulations with CESM including and excluding interactive vegetation (the “interactive vegetation” set; Table 2) to investigate its importance for Siberian temperatures. We find that the vegetation–climate
feedback leads to a large LGM JJA cooling over Siberia, which is even more pronounced when using the CAM5 atmospheric model instead of CAM4 (Fig. 7 and Table 3). If vegetation is allowed to respond to the changing climate through carbon–nitrogen dynamics, the tree and shrub limits shift south by several degrees of latitude as shown by the leaf area index (Fig. 8a and c). In CESM, the presence of vegetation, its height as well as its density have a large impact on the surface albedo through the vegetation–albedo feedback: vegetation that protrudes through the snowpack lowers the surface albedo that in turn leads to a positive feedback loop with increasing temperatures, more snowmelt, more vegetation growth and an even lower surface albedo. Accordingly, the situation in the CESM simulations including interactive vegetation is such that the cold and snow-covered landscape limits vegetation growth and leads to a southward migration of the tree and shrub limits. This relationship between vegetation and snow cover also determines the resulting LGM JJA temperature changes (compare Fig. 7a and c; Table 3). Previous studies also found an important role of vegetation feedbacks in defining LGM Arctic temperatures (Jahn et al., 2005). The impact of interactive vegetation in CESM is also clearly seen in the PI simulations, resulting in a substantial decrease in the leaf area index with respect to the prescribed values (Fig. 8a and b) and is in line with the cold bias in modeled Siberian surface temperatures described by Lawrence et al. (2011) (see also Table 3).

Looking at all the experiments in the third set of experiments (“interactive vegetation”; Table 2), using different atmospheric model physics (Fig. 6) with or without interactive vegetation (Fig. 7), we find that the strong cooling in Siberia in the simulation that combines both the dif-
ferent atmospheric model physics and interactive vegetation (LGM_CAM5_Veg; Fig. 7b) is not readily explained as a linear combination of the two individual effects. This is true for Siberian JJA temperatures but also for other key climate variables (Table 3). It should be noted that the simulations with the lowest JJA LGM temperatures in Table 3 are in fact the ones with the highest precipitation rates (not only in JJA but also in the annual mean; not shown). This all shows the complexity of the response to a combination of factors, in this case changes in large-scale atmospheric circulation, local atmospheric processes and local land-surface processes. It is to be expected that the response of individual PMIP simulations is similarly complex.

4 Concluding remarks

From a climate model perspective, LGM JJA temperatures in northeastern Siberia appear highly susceptible to changes in the imposed boundary conditions, included feedbacks and processes, and the model physics of the different climate model components, much more so for Siberia than for any other region. This becomes apparent from the comparison of 17 different PMIP2 and PMIP3 LGM experiments, as well as from three sets of CESM sensitivity experiments. The spread in Siberian JJA LGM temperature anomalies in the CESM ensemble is ≈ 20 °C, which is comparable to the intermodel spread of ≈ 24 °C found in the PMIP simulations. The main cause appears to be that relatively small changes in the continental ice sheets or model physics can lead to large changes in meridional atmospheric heat transport related to changes in the circumpolar atmospheric stationary wave pattern, in line with Ullman et al. (2014) and Liakka and Lofverstrom (2018). Local snow–albedo and vegetation–climate feedbacks strongly amplify the Siberian JJA temperature change. Recently, Schenk et al. (2018) showed that the spatial resolution of the atmospheric model is key to obtaining realistic glacial temperature anomalies. However, we do not find any correlation between atmospheric model resolution and Siberian JJA LGM temperature anomalies (Table 1), despite having some models with a resolution very similar to the one used by Schenk et al. (2018). We note, however, that we did not perform a dedicated sensitivity experiment, changing only the spatial resolution while keeping all other factors the same.

In most of the examined PMIP LGM simulations, Siberia receives less precipitation; however, we do not find indications that the buildup of a Siberian ice sheet was hampered by the absence of precipitation. On the contrary, in both the PMIP ensemble and our CESM experiments, we find that local precipitation and JJA temperature changes are not significantly correlated, while cooler summers are strongly correlated to a higher snow cover, suggesting that a cold climate would be associated with a perennial snow cover. We also do not find support for the notion that changes in large-scale atmospheric stationary wave patterns drive Siberian JJA temperatures directly through local cloud changes.

Although situated at high northern latitudes, geological evidence suggests that Siberia was covered by continental ice sheets during some glacial periods but remained largely ice free during others, for instance, the last glacial period including the LGM. Increased atmospheric dust deposition and a precipitation shadow cast by the Eurasian ice sheets to the west are often listed as possible causes; however, such mechanisms cannot readily explain the absence of a Siberian ice sheet in some glacial periods but its presence in others, or conform with the independent reconstructions of Siberian LGM summer temperatures close to present-day values (Meyer et al., 2017). This is suggesting that these processes are likely only part of the story, and here we argue for the importance of changes in meridional atmospheric heat transport and the configuration of the Northern Hemisphere continental ice sheets in order to understand the geological evidence. The combination of these factors, accompanied by local feedbacks can lead to strongly divergent summer temperatures in the region, which during some glacial periods could have been sufficiently low to allow for the buildup of an ice sheet, while during other glacial periods, above-freezing summer temperatures might have prevented a multi-year snowpack, and hence an ice sheet, from forming. Finally, this high sensitivity of Siberian LGM summer temperatures in different climate models will present a major challenge in future modeling efforts using coupled ice-sheet–climate models.
