11:45 Transit to Cuxhaven,

Th. 12.07.2018

Weather: Sunny
09:30 Arrival in Cuxhaven; disembarking equipment

3. Introduction

The research cruise AL-511 was part of the research project "Nordfriesland Süd – Der geologisch/sedimentologische Aufbau und die Habitatverteilung im Übergangsbereich Watt – Schelf zwischen der Amrumbank und der Eiderinne" (the geological / geological built up and the habitat distribution between Amrum Bank and Eider channel)", which is a cooperation between the Agency for Coastal Protection, National Park and Marine Conservation of Schleswig-Holstein (LKN), the State Office for Agriculture, Environment and Rural Areas Schleswig-Holstein (LLUR) and the Institute of Geosciences (working groups Coastal Geology and Sedimentology; Hydroacoustics and Marine Geophysics) of Kiel University (CAU). The cruise AL-511 is a follow up of previous cruises (L17-08, AL496, L18-06) which have been carried out in the frame of the same project.

Main objective of cruise AL-511 was the acquisition of high resolution hydroacoustic data (Figure 1 shows the tracklines of all hydroacoustic profiles) and sediment data to obtain information about the interdependence and interactions between geological structures in the subsurface, the physical properties of the seafloor (morphology and sediment distribution), the hydrodynamic conditions of tides and the setting in the water column. Two areas at the distal part of the two tidal channels Süderhever and Eider have been mapped repetitive. By collecting sediment samples with a HELCOM grab sampler and giant box corer, a special focus was put on the distribution of the razor clams of the genus *Ensis*.

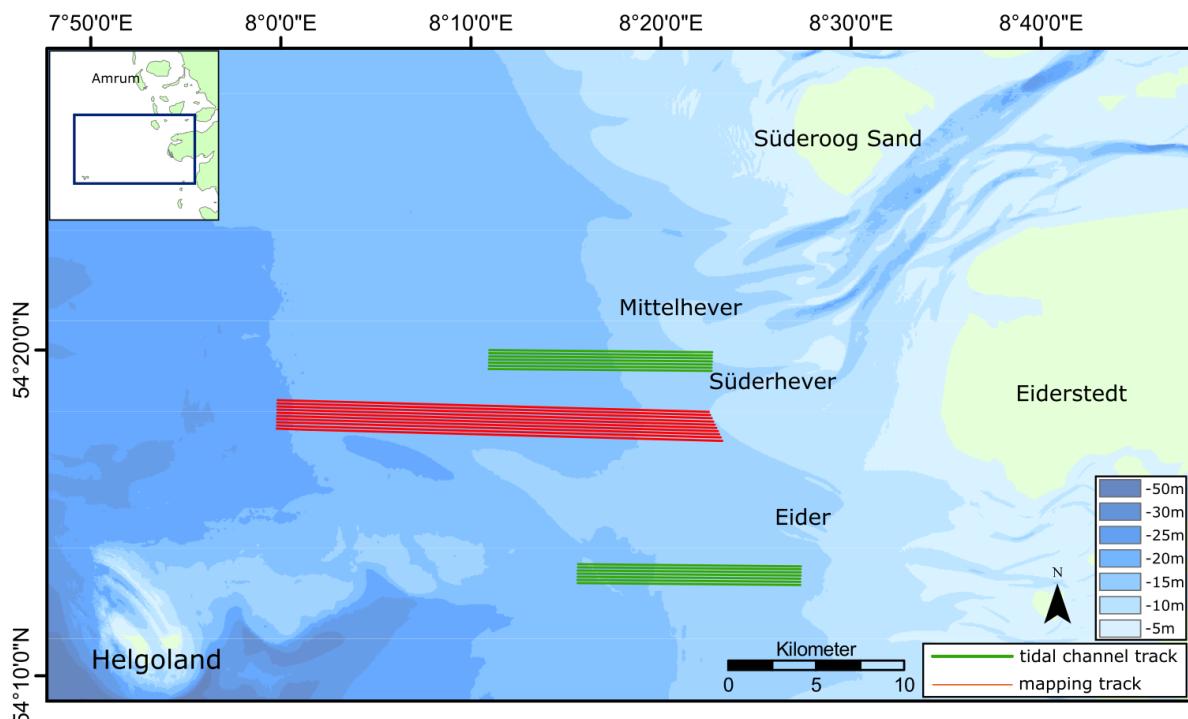

Figure 1: Investigation area and track lines. The green lines show the repeated SSS-survey lines to investigate the stability of bedforms and sediment distribution patterns during a whole spring – neap tidal cycle. The red lines show track lines that were not completed during the cruise L18-06 in May/June 2018. Whenever there was time, this mapping was continued.

4. Methods

To obtain information about the sedimentological and geological built up of the seafloor, hydroacoustic data was acquired by applying the towed dual frequency (100 and 400 kHz) Teledyne Benthos SIS 1624 Sidescan Sonar System (SSS) (see Figure 2).

Figure 2: Overview of some of the used methods /from left to right): Sidescan sonar system attached to bouncy element, underwater video camera, HELCOM grab sampler, giant box corer.

For towing the SSS-System and data transfer a McArtney Cormac 4 winch was used. In between the towfish and the winch, a depressor weight serves for absorbing abrupt tensile forces on the SSS due to waves and ships movement. This towing configuration keeps the sonar system in a constant depth (Figure 3).

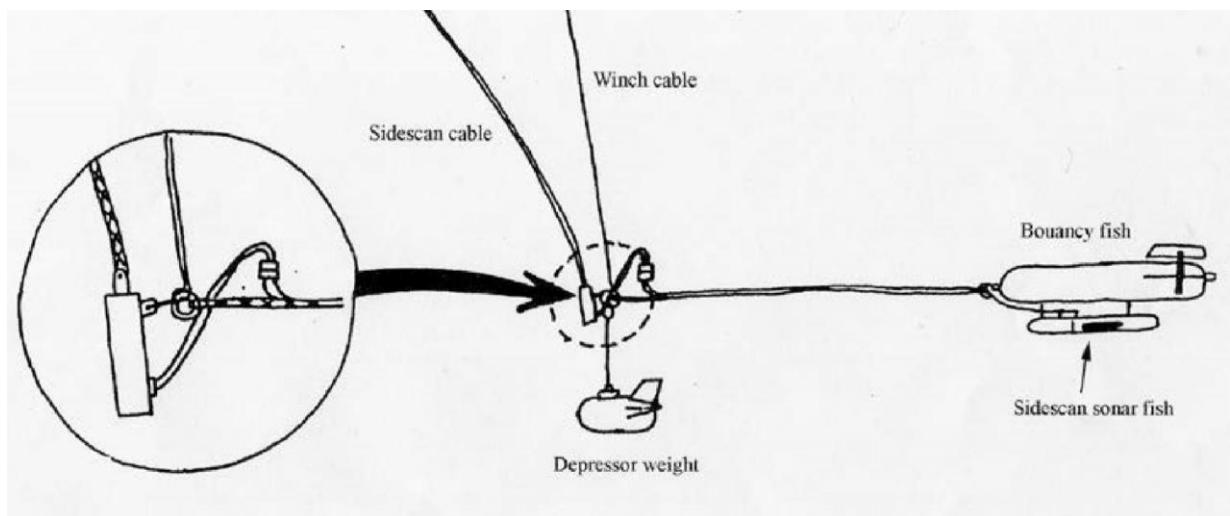

Figure 3: Towing configuration including a depressor weight for improving stability of SSS (Schwarzer and Wittbrodt, 2017).

By measuring the intensities of the backscattering acoustic signal, it is possible to draw conclusions about morphology and properties of the seafloor and sometimes the distribution of certain benthic species (Blondel & Murton, 1997; Lurton, 2002; Blondel, 2009). The range across track was set to 100 m to each side. Line spacing between the profiles was around 180m which results in a full coverage map with an overlap of about 20 m. After post-processing the data, high resolving acoustic images of the SSS can be used to elaborate geological facies of the seafloor (Lurton, 2002).

For ground truthing, sediment samples were collected with a HELCOM grab sampler (GS). By using an underwater video system, it is possible to get rough information about morphological structures, concentration of particles in suspension and benthic population on the seafloor. In order to gain more detailed information about the sea floor a giant box corer (GBC) was applied. The advantage of this method is that a lot of undisturbed material (structure of sediment layers are preserved) can be collected with one single grab. In addition this device penetrates deeper into the sediment compared to the HELCOM grab. Benthic organisms living in deeper layers can be sampled applying this method. Figure 4 shows the position of all sampling stations.

A high resolution parametric sediment echosounder (INNOMAR SES-2000 medium) operating with 100 kHz as primary (85 – 115 kHz frequency band for the second primary frequency) and resulting 8 kHz as secondary frequency, was applied to obtain further information about the subsurface built-up. According to Wunderlich & Müller (2003) the vertical resolution is smaller than 6 cm. During hydroacoustic measurements the vessel speed did not exceed 4.5 knots.

Current measurements were done by applying an Acoustic Doppler current profiler (ADCP).

In order to calibrate the hydroacoustic recordings, CTD-measurements were carried out regularly. Furthermore an optical sensor for measuring the turbidity was attached to the CTD-probe.

The data set focuses on three local areas. Two areas (of 13,2 and 14,4 km² in size) are located in the outer parts of the two tidal channels Süderhever and Eider. Landward limitation was due to low water-depth. In order to examine the hydrodynamic influence on sediment and habitat distribution, repeated measurements were carried out.

Additionally, residual tracks belonging to the research cruise L18-06 were mapped whenever it was possible to benefit from time gaps (see mapping track (red lines) in Figure 1).

5. Preliminary scientific results

Merged in an overview, the SSS mosaics show changes in backscatter intensity striking NW to SE (black arrows in Figure 4), what seems to correlate with the contour lines of the bathymetry. In several sediment samples descending from the NW–SE striking sections with higher backscatter intensity the polychaete *Lanice conchilega* was found. *L. conchilega* is a tube building worm using sand grains and shell fragments as construction element (see Figure 5). *L. conchilega* colonies (e.g. seen in underwater video footage in Figure 6) have an impact on the roughness of the sea floor and thus can be detected in Side-Scan Sonar im-

ages (Heinrich et al., 2017). Possibly the data shows preferred zones for *L. conchilega* colonies dependent on water depth slope of the sea floor and hydrodynamic conditions.

Concerning repeated measurements in the area of the tidal channels, many structures can be detected in different measurement cycles, which indicates that over small time scales they are more or less stable in their location and form (see Figure 7). A quantitative analysis, visualizing the changes should be done in further work.

Almost all GBC samples contained high numbers of the razor clam *Ensis* sp.. Partially *Ensis directus* which is an invasive species, originally living at the east coast of the United States and invaded into the North Sea in the late seventies by transport in ballast tanks of container ships (von Cosel, 1982) could be identified. For seven GBC sediment samples, the distribution of *Ensis* sp. was documented regarding their occurrence and their sizes. *Ensis* sp. larger than 3 cm are rarely seen in HELCOM grab samples, which is linked to a smaller penetration depth in combination with quickly (up to 1 cm/sec) into the deeper parts of the sediment fleeing razor clams (Alexander, 1979, Tulp et al. 2010, Winter and Hosoi, 2011). In Figure 8 (right picture) a 15 cm deep trace of escape can be observed in a GBC sample.

Figure 9 shows some CTD data collected in the area of the Eider tidal channel. Temperature gradients over the depth are not observable.

SES-data was collected in order to investigate the vertical architecture of the seafloor and to investigate whether there are links between surface morphology and subsurficial geological built up. Figure 10 shows three examples of west-east striking SES-profiles. For example extraordinary differences between seafloor- heights along the profile of Figure 10a can partly be linked to distinct dipping reflectors in the subsurface. At some locations, where dipping reflectors are cut by the surface, clearly coarser material (gravel) lies on the seafloor. Coarser material depicts as dark patches in des SSS- mosaic.

In contrast, clear geological structures which do not influence the surface morphology can be seen in Figure 10b. Structures, representing incised valleys can be observed below a more or less horizontal reflector. The horizontal reflector cut the valleys at their upper end indicating an erosive horizon, which is overlain by transgressive marine deposits. The marine sediments are displayed in greenish colours. Their internal reflections, caused by small-scaled local density differences and layers of shell fragments, create a distinct seismic picture. These sediments build up the uppermost meter of the marine deposits in this location.

Figure 10c shows a pronounced, small scaled morphology at the surface. This increase of surface- roughness can produce differences in the backscatter of an SSS on the one hand, and influences the sediment dynamics on the other hand. The increased roughness may be a product of high biological activity. A further difference to the other two SES- profiles is the clear horizontal stratification of sediment layers, indicated by various small reflectors close to the surface. Trapped gas limits the penetration depth of seismic waves. Therefore, the eastern part of the profile shows less horizontal layers, but blur parts up to 13 m depth.

7. Appendix

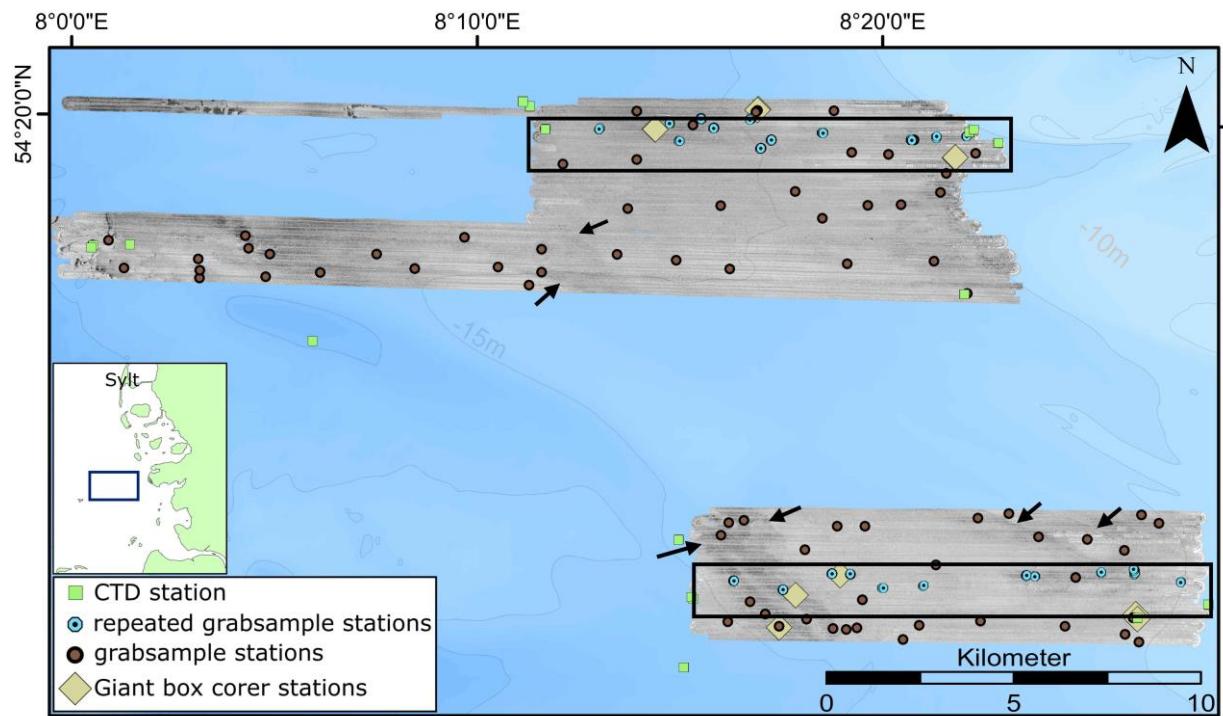

Figure 4: View of combined surface data. The black rectangles show the subsections where repeated measurements have been done (north: Hever, south: Eider). Black arrows highlight NW-SE striking variations in backscatter intensities.

Figure 5: *L. conchilega* tubes can reach a length of up to 40 cm (Ziegelmeier 1969). The adult species (present example was taken from box corer sample AL511_20180702_GKG_1) can include bigger shell fragments in the tube's structure.

Figure 6: *L. conchilega* colony in underwater video recording. On top, several starfish can be seen.

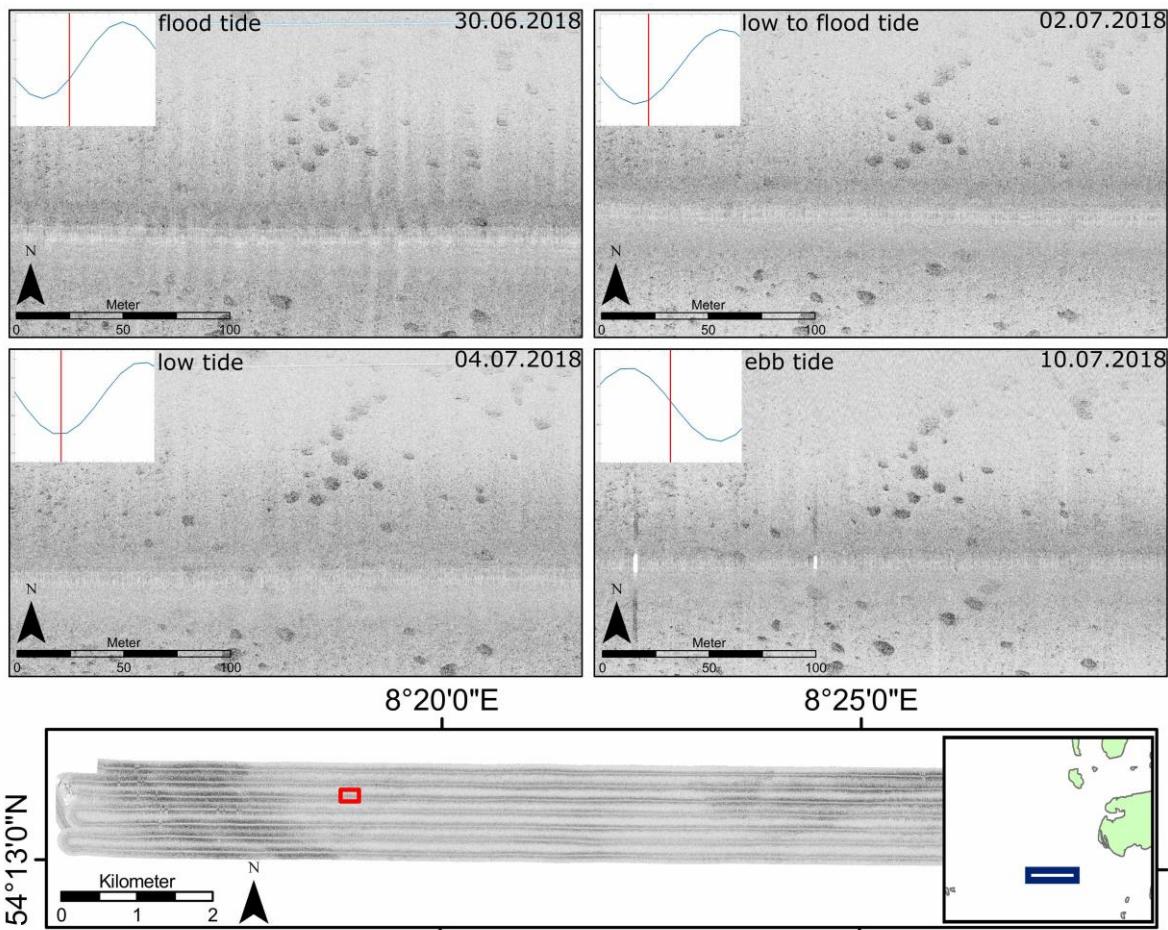

Figure 7: Rough comparison of repeated measurements for a subsection in the Eider channel. The location of the subsection is highlighted by the red rectangle. Illustration top left in each subsection-measurement indicates the tidal condition during recording. Some structures seem to be very persistent over the tidal cycle.

Figure 8: Giant box corer sediment sample AL-511-GKG_20170702_1 from Hever tidal channel ($54^{\circ} 19,904'N$ $8^{\circ} 14,388'E$). *Ensis* sp. burrows can be observed down to 15cm. *Ensis* sp. is capable to quickly pull itself back into the sediment.

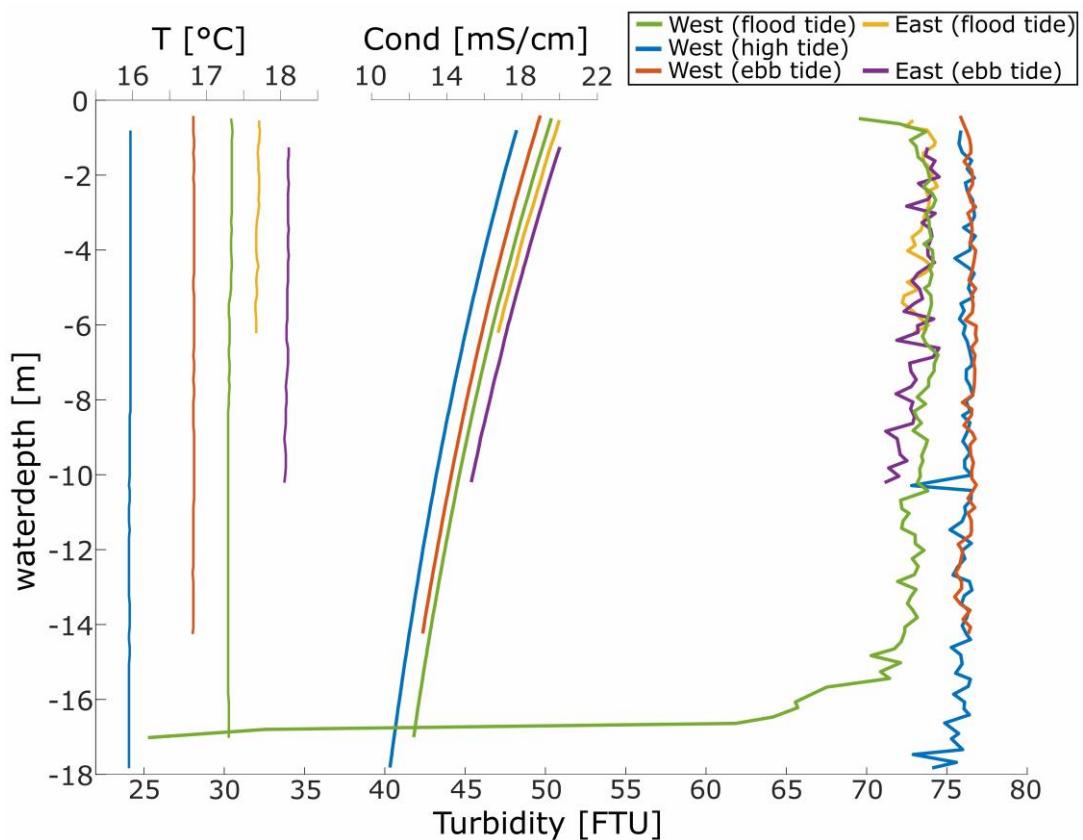

Figure 9: CTD measurements located in the area in front of the Eider tidal channel. For calibration water-samples were taken in different depths. The profiles show temperature, conductivity and turbidity over depth.

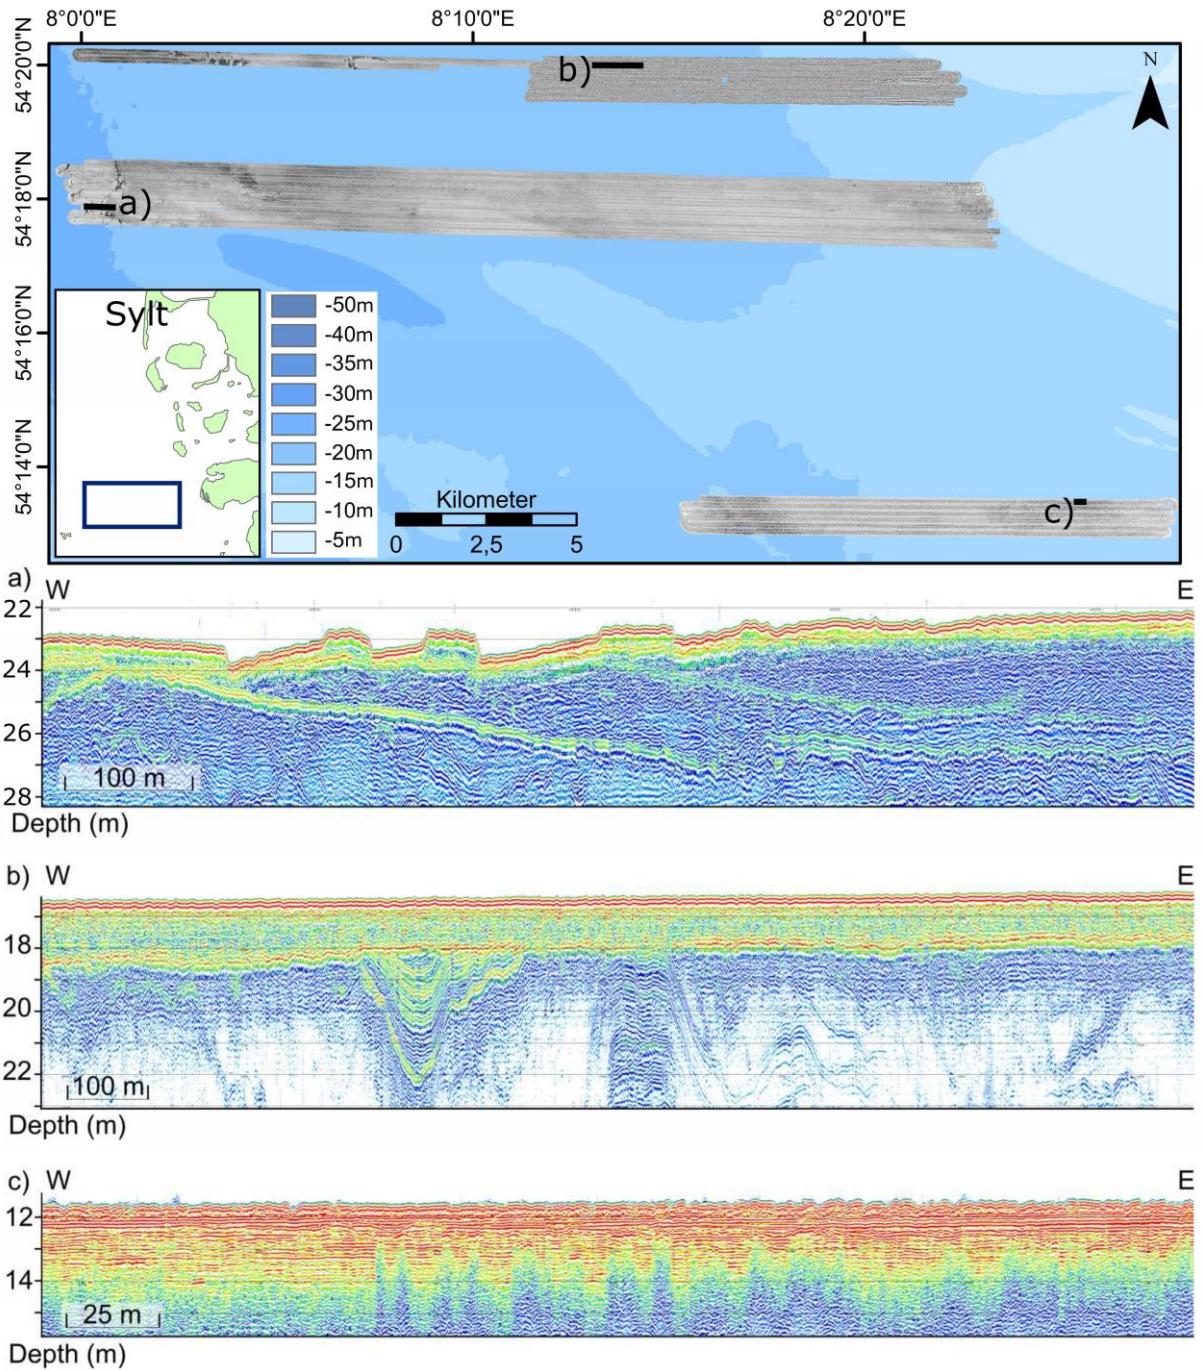

Figure 10: Three different SES Profiles at different locations: a) dipping reflectors that may influence the surface morphology; b) layered depression- like structures that are incised into a deeper seismic unit. The upper seismic layer appears chaotic, in contrast to c) horizontal reflectors near the surface and a pronounced, choppy surface morphology.
